Dynamical Adjustment

The atmospheric response to latent heat depends on the horizontal scale of the heating relative to the Rossby radius of deformation, L_R , where

$$L_R = \frac{C_N}{(\zeta + f)^{\frac{1}{2}}(2VR^{-1} + f)^{\frac{1}{2}}}$$

ζ is the vertical component of relative vorticity, f is the Coriolis parameter, C_N is the phase speed of an inertial gravity wave, and V is the tangential component of the wind at the radius of curvature, R . If the horizontal scale of heating is less than L_R , then most of the energy released by heating will propagate away from the disturbance as gravity waves. If the scale of the latent heating is close to or exceeds L_R , then energy maintains nearly geostrophically balanced flow. For midlatitude systems, L_R is about 300 km, close to MCC length scale, explaining their longevity and ability to influence the large-scale circulation.

Diabatic heating in MCCs forces upper-level jet streaks downstream by enhancing ageostrophic flow in the jet entrance. Dynamical adjustment to the 1993 US MCSs created an upper-level wind maximum to the northeast of the heaviest precipitation, upper-level divergence over the region of heaviest rainfall, and an anomalously strong southerly low-level flow into the Upper Midwest. Thus, a continental-scale adjustment favored more convection and flooding.

Mesoscale Convective Vortices

Since the late 1970s, researchers have observed spiral bands of midlevel clouds that remain after the decay of MCSs, appearing like a tropical cyclone on land (e.g., Figure 13). The cyclonic circulation is centered on a warm-core, MCV that sometimes develops in the stratiform region of MCSs (Figure 14).

The development can be examined in terms of potential vorticity (PV) theory, which dictates that mass-integrated PV remains constant between two isentropic surfaces regardless of changes in mass transport or diabatic heating. Therefore, when diabatic heating occurs in moist convection, evacuation of mass across isentropes will lead to an increase in PV, i.e., the spin of the fluid adjusts to changes in the depth of the rotating column. *Heating in the positive PV anomaly can persist for days, regenerating convection and amplifying the vortex.* Under certain conditions, series of MCSs form in roughly the same location and follow similar tracks, thereby aggravating their flood potential, e.g., during the 1993 US Midwest Floods.

Tropical Cyclone Effects

It has been theorized that when successive cycles of convection occur over a warm water surface, they can play a crucial role in the transition of a loosely organized cluster of convection into a tropical depression, provided the large-scale environment is conducive. Tropical cyclones sometimes form when MCSs move over water, probably due to midlevel vortices extending downward.

Most tropical cyclone circulations are synoptic scale but their precipitation structure and inner core dynamics are predominantly mesoscale. Radar and satellite microwave

measurements suggest that mesoscale convective bursts can lead to rapid changes in cyclone intensity and structure through latent heat feedback mechanisms that enhance convergence and vorticity. Tropical Cyclone Oliver (1993) is a well-documented case of tropical cyclone genesis from MCSs.

Radiative Balance

One of the most important aspects of deep convection is its influence on the tropospheric radiation budget. The radiation balance depends on the distribution and characteristics of hydrometeors and other cloud particles. A tropical MCS can

cause net cooling from solar extinction, outweighing warming inside the system. Differential radiative heating can alter the evolution and mass circulation of individual MCSs through feedback among latent heat release, convective updrafts, and precipitation.

The time of day that MCSs occur can have varying radiative effects. Even with constant total cloud fraction, the sign of the radiation balance is sensitive to the diurnal distribution of deep convective cloud systems. For example, warming due to increased nocturnal deep convective cloud fraction exceeded the shortwave cooling over North America (July 1985 and 1986 comparison).

The diurnal radiative cycle modulates tropical oceanic convection, which attains peak intensity near sunrise. One hypothesis for the overnight growth holds that horizontal divergence in the radiation field near MCSs can lead to mass circulation that enhances cloud development. Another theory suggests that long-wave cooling at the cloud top and warming at cloud base lead to destabilization and increased convection.

Chemical Transport

Mesoscale convection is important for the transport and chemical cycling of trace gases. The convective updraft displaces the tropopause upward leading to strong vertical mixing. In one US MCC, an anvil formed *within the stratosphere* resulting in a layer of tropospheric air approximately one kilometer thick lying above an equally thick layer of stratospheric air. This displacement, along with a broken tropopause around the edges, injected stratospheric ozone into the troposphere and ozone-poor tropospheric air into the stratosphere. During the Stratosphere–Troposphere Analyses of Regional Transport (2008), convective injections were observed up to 5 km above the stratospheric intrusion base.

In the Amazon Boundary Layer Experiment, ozone concentrations in the mid- to upper levels of squall lines were 3–4 times above background values. MCCs often occur in series, disturbing atmospheric thermal and trace gas fields over a large area, making them likely important local, natural sources of tropospheric ozone in MCC populated regions.

Atmospheric Electrical Effects

Since the early 1990s interest has grown in the electrical properties of MCSs, particularly their association with upper atmospheric transient luminous events known as sprites, blue jets, and elves. These features are observed above the stratiform precipitation region of large MCSs that support horizontally extensive and layered regions of positive charge generation (in contrast to convective elements that are predominantly negatively charged). Over the US Great Plains, a necessary but not sufficient condition for sprites is an MCS with stratiform precipitation area over 20 000 km². Sprites are observed in other MCS-favored zones but indications are that sprites are less frequent on a per storm basis in tropical systems. These discoveries provide more incentives for continued investigation of MCSs.

Appendix

Glossary of Thermodynamic Parameters

Convective Available Potential Energy (J Kg⁻¹)

CAPE is the vertically integrated positive buoyancy of an adiabatically rising parcel, an excellent measure of latent instability. Increasing values of CAPE generally lead to progressively, more vigorous convection. CAPE depends on the parcel chosen for lifting and on whether the initial lift is mechanically forced or from surface heating. CAPE is represented on a thermodynamic diagram (Skew-*T*) as the positive area between the moist adiabatic curve and the sounding temperature curve, from the level of free convection to the equilibrium level.

$$\text{CAPE} = g \int_{z_{\text{LFC}}}^{z_{\text{EL}}} \left(\frac{T_p - T_e}{T_e} \right) dz$$

K-Index (KI, °C)

The K-Index has been shown to be particularly useful for identifying convective and heavy rain-producing environments because it accounts for the differences in moisture not simply temperature. George's (1960) results indicate that thunderstorm probability ranges from near zero when $K < 20$ to widespread activity when $K > 35$.

$$\text{KI} = (T_{850} - T_{500}) + Td_{850} - Tdd_{700},$$

where Td is the dewpoint temperature and Tdd is the dewpoint depression.

Synopsis

The fundamentals of downdrafts with an emphasis on those events, referred to as microbursts, that produce strong outflow winds near the surface are discussed.

Introduction

The atmosphere undergoes a dramatic overturning when a convective storm forms. Warm, moist air in the boundary layer is transported aloft, while relatively cool and dry air is brought down to the lowest levels. The primary mechanism that transports the latter air mass to the boundary layer is the downdraft. The thermodynamic conditions of the downdraft are familiar to the general public once it reaches the surface by the respite from hot, humid conditions that are prevalent in the ambient air that is convectively unstable. The leading edge of this outflow is referred to as the gust front.

Many convective downdrafts do not produce strong winds at the surface; however, in some instances the downward velocities and subsequent outflow winds can result in severe damage. Indeed, these strong winds can result in considerable crop, tree, and structural damage and have been identified as a causal factor in a number of aircraft accidents. These intense wind events are called downbursts and are defined as an area of strong winds produced by a downdraft over an area from <1 to 10 km in horizontal dimensions. Downbursts can be further subdivided into macrobursts and microbursts with the following definitions.

- *Microburst.* Small downburst, less than 4 km in outflow diameter at the ground, with peak winds lasting only 2–5 min. They may induce dangerous tailwind and downflow wind shears which can reduce aircraft performance.
- *Macroburst.* Large downburst, with 4 km or larger outflow diameter at the ground; damaging wind lasts 5–20 min. An intense macroburst causes tornado-force damage up to EF3 intensity (on the Enhanced Fujita scale of damage intensity). (The EF-scale rates the damage intensity of tornadoes and ranges from EF1 to EF5. A rating of EF5 has been associated with the most intense tornadoes.)

It is the former phenomenon that has garnered the most interest, owing to its small temporal and spatial scales. Indeed, during the period 1974–85, microburst winds were a factor in at least 11 civil transport accidents and incidents in the United States, involving over 400 fatalities and 145 injuries. Extensive research has been focused on documenting the reasons why this small subset of downdrafts produces damaging winds.

Fundamentals of the Downdraft

In order to understand the microburst phenomena, it is instructive to describe the fundamental characteristics of the downdraft

and how it differs from the updraft. A naive view of the downdraft is that it is an upside-down version of the updraft; however, this is far from an accurate description. While the updraft is typically slightly supersaturated, the downdraft is often appreciably subsaturated, owing to the inability for condensate cooling by evaporation, melting, or sublimation to offset completely the warming from adiabatic compression. For a number of years this was, perhaps, one of the greatest misconceptions of the thermodynamic characteristics within the downdraft. It was often assumed that downdraft air parcels descended moist adiabatically (i.e., assumed saturated descent). The wet-bulb temperature was also believed to be representative of the temperature within a descending air parcel. It is now known that the saturated wet adiabat can only be approached by the downdraft if it is weak (this allows sufficient time for latent cooling to offset adiabatic compression during descent), the mean drop size is small (see discussion below), or the rainfall is heavy.

It is more important to document the microphysical details of the liquid or solid condensate within the downdraft than within the updraft. For example, for a prescribed water content, small raindrops are more conducive to producing stronger downdrafts than large drops for two reasons: (1) there is greater surface area exposed to the environment; and (2) smaller drops have greater curvature which results in a larger equilibrium vapor pressure and, hence, lower relative humidity. Both effects increase the potential for evaporation, resulting in latent cooling. Finally, individual parcel vertical excursions tend to be less than 4 km for downdrafts and often greater than 10 km (i.e., the depth of the troposphere) for updrafts. The primary reason for this difference in length scale is that the positive buoyancy in the updraft is much greater than the negative buoyancy in the downdraft.

The forcing mechanisms of the microburst can be understood by considering the inviscid vertical momentum equation

$$\frac{d\bar{w}}{dt} = -\frac{1}{\rho} \frac{\partial \bar{p}}{\partial z} + g \left(\frac{\theta'_v}{\theta_{v0}} - \frac{c_v}{c_p} \frac{p'}{p_0} - (r_c + r_r + r_i) \right) \quad [1]$$

(1) (2) (3) (4)

where $\bar{w}$ is the mean vertical velocity, p the pressure, θ'_v the virtual potential temperature, c_p the specific heat at constant pressure, c_v the specific heat at constant volume, r_c the mixing ratio of cloud water, r_r the mixing ratio of rainwater, and r_i the mixing ratio of ice water.

The primes denote departures from a basic state (subscript 0), which varies only in height.

Term 1 is the vertical gradient of perturbation pressure. Term 2 represents thermal buoyancy accounted for in parcel theory and term 3 is the perturbation pressure buoyancy. Condensate

loading of cloud, rain, and ice water is represented by term 4. In addition, entrainment (or mixing) of environmental air with cloudy air or precipitation has been shown to be an important factor in downdraft dynamics.

The vertical gradient of perturbation pressure is generally small for most downdrafts; however, its effect becomes significant in intense cumulonimbi and mesoscale convective systems associated with strong vertical wind shear. Strong downdrafts can develop owing to rapid pressure falls generated in response to an intensifying low-level mesocyclone within a supercell thunderstorm.

The effect of thermal buoyancy is the best-known term in the vertical momentum equation. Relatively cold (hot) air promotes negative (positive) vertical velocities. The importance of using virtual potential temperature in the vertical momentum equation has been shown. Increasing the environmental relative humidity at low levels increases the virtual temperature difference and will lead to stronger downdrafts even if the ambient air temperature remains the same. The pressure buoyancy term suggests that a downdraft will be produced if an air parcel has a higher perturbation pressure than its surroundings. This effect is ignored in classical parcel theory, which assumes that the environmental and parcel pressures are equal. In general, this effect is relatively small in comparison to thermal buoyancy and the pressure gradient effects.

Some of the early hypotheses on downdrafts suggested that the air was initially dragged downward by the weight of precipitation particles (term 4 in eqn [1]), and then cooled by evaporation. This has been reinforced by numerous studies that have examined the forcing mechanisms of downdrafts. While precipitation drag can be important in initiating a downdraft, the critical role of latent cooling produced via evaporation can be shown by considering a case where the water mixing ratio is evaporated completely. A water content of 1 g kg^{-1} is approximately equivalent to a temperature deficit of 0.30°C in the buoyancy term in eqn [1]. If this water mixing ratio evaporates then the resulting temperature deficit is given by

$$\theta'_v = L \frac{r_r}{c_p} \approx 2.5 \text{ K} \quad [2]$$

where L is the latent heat of evaporation.

Thus, the temperature deficit has increased by a factor of 8.3 or nearly an order of magnitude by evaporating the water. Accordingly, the evaporation of raindrops rather than water loading would be more effective in accelerating a downdraft.

The effect of entrainment is complex. At higher levels, the entrainment of dry air promotes downdrafts by evaporation or sublimation of cloudy air and precipitation, especially when the entrained region corresponds to the level of minimum equivalent or wet-bulb potential temperature. The effect of entrainment is different at lower levels once a downdraft forms. If the downdraft is driven primarily by negative thermal buoyancy then its intensity will be determined by the virtual temperature difference between the descending air parcel and the environment as shown in eqn [1]. Mixing of environmental air at this stage will deplete the negative buoyancy by decreasing this difference and will lead to reduced downdraft speeds.

Figure 1 Schematic diagram illustrating the impact of a microburst on aircraft performance during takeoff. The airplane first encounters a headwind and first experiences added lift. This is followed in short succession by a decreasing headwind component, a downdraft, and finally a strong tailwind which may lead to an impact with the ground. Composite drawing based on numerous studies of aircraft accidents. Reproduced from Fujita, T.T., 1985. *The Downburst – Microburst and Macroburst*. SMRP Research Paper No. 210, NTIS PB-148880, report of Projects NIMROD and JAWS. University of Chicago Printing Department, Chicago, IL.

The Microburst

The discovery of the microburst can be traced back to a series of aircraft accidents and the existence of small-scale divergent damage patterns in crops and forests discovered after the passage of a thunderstorm. Both events were shown to be a result of a transient but intense downdraft accompanied by strong outflow. The typical scenario for a microburst-related aircraft accident is shown in Figure 1. When an aircraft flies through a microburst during takeoff it first encounters a headwind component from the microburst outflow. This headwind increases lift by increasing the relative airflow over the wing. The plane may then pitch up, and the pilot may attempt to compensate by leveling off. But only a matter of seconds later the plane encounters a decreasing headwind, downdraft (within the center of the microburst), and then a strong tailwind. The plane has lost lift and could find itself flying too low and with insufficient air speed to avoid a crash. A similar scenario could be created when an aircraft is on approach for a landing at an airport.

The conceptual model of the descending microburst is shown in Figure 2. The microburst is characterized by a shaft of strong downward velocity. It is also associated with strong divergent flow at its center when it reaches the ground, and is

Figure 2 Conceptual model of a microburst hypothesized to explain ground-damage patterns. Three stages of development are shown. The regions of high wind within the rotor are indicated. Reproduced from Fujita, T.T., 1985. *The Downburst – Microburst and Macroburst*. SMRP Research Paper No. 210, NTIS PB-148880, report of Projects NIMROD and JAWS. University of Chicago Printing Department, Chicago, IL.

Figure 3 Three-dimensional visualization of a microburst. Reproduced from Fujita, T.T., 1985. *The Downburst – Microburst and Macrobust*. SMRP Research Paper No. 210, NTIS PB-148880, report of Projects NIMROD and JAWS. University of Chicago Printing Department, Chicago, IL.

followed by an accelerating outburst of strong winds in an overturning rotor propagating away from the center of the microburst. The highest wind speeds are usually associated with these rotors with the peak speeds occurring in the lower portion of the ring vortex, where outflow speeds are augmented by the circulation of the ring. The mechanism for intensifying the outflow winds is the stretching of the vortex as the ring expands. Horizontal pressure gradients can also contribute to high-outflow wind speeds, as discussed below. The vertical gradient of perturbation pressure (refer to eqn [1]) appears to play a relatively minor role in most microbursts. The exception appears to be the microburst associated with the supercell storm. Microburst damage has been frequently documented very near tornado damage tracks. Minimum pressures within the low-level mesocyclones are believed to enhance the downward velocities in these downdrafts.

The microburst in three dimensions is shown schematically in Figure 3. A key feature in the figure is that a number of microbursts are associated with small-scale circulations aloft. In fact, it is common for many microbursts to rotate, with the strongest ones associated with stronger rotation. The magnitude of the vertical vorticity within these circulations can be comparable to the vorticity present in the parent mesocyclone associated with a tornado.

Results from numerous observational and numerical studies suggest that microburst winds are associated with a continuum of rain rates that range from heavy precipitation from thunderstorms to virga shafts from either altocumuli, or clouds that have been referred to as shallow, high-based cumulonimbi. New definitions were created to account for the following two extreme microphysical situations.

- *Dry/low-reflectivity microburst.* A microburst associated with <0.25 mm of rain or a radar echo <35 dBZ in intensity.
- *Wet/high-reflectivity microburst.* A microburst associated with 0.25 mm of rain or a radar echo >35 dBZ in intensity.

Low-Reflectivity or Dry Microburst

Numerical simulations have shown the sensitivity of downdraft intensity as a function of drop size, rain intensity, and subcloud lapse rate. One of their conclusions is that when the

environmental lapse rate is approximately equal to the dry adiabatic lapse rate then the rates of evaporation place little restriction on the downdraft magnitude, and even in light precipitation there may be strong downdrafts generated. In the absence of pressure effects and in light rain situations (i.e., dry microbursts), it is often convenient to view the maintenance of the downdraft as the competing forces of cooling due to evaporation and sublimation versus dry adiabatic warming due to compression. When the subcloud lapse rate is dry adiabatic, any cooling by condensate results in a negative temperature perturbation that will maintain the downdraft. This effect increases with the depth of dry adiabatic lapse rate. Compressional warming in a descending parcel can counteract this cooling when the subcloud lapse rate is less than dry adiabatic. Condensate loading plays a relatively minor role in producing dry microbursts because only light precipitation is present.

These results have been confirmed by observations of virga shafts from weakly precipitating cloud systems producing low-reflectivity microbursts. These microbursts are particularly hazardous to aircraft because the parent cloud and pendant virga shafts appear innocuous. The weak echoes and low precipitation rates often result in little or no temperature change at the surface. In some cases, the air temperature has been shown to rise although the virtual temperature typically falls. Figure 4 is a plot of microburst occurrence as a function of radar reflectivity and subcloud lapse rate. Each point on the figure represents a microburst event identified by Doppler radar. Microbursts can be seen to occur most frequently at lapse rates of temperature exceeding $\sim 8.5 \text{ K km}^{-1}$. Practically no microbursts occurred for lapse rates less than $\sim 8.0 \text{ K km}^{-1}$. The axial profiles for cooling owing to phase change of condensate for the dry microburst is shown in Figure 5. The dry microburst is associated with small cooling, but it occurs through a deep column. Thus the integrated negative buoyancy is large. The prevalence of dry microburst over the high plains of the United States is attributed largely to the deep, dry adiabatic layer characteristic of this geographic region.

A simple model of evaporatively driven downdraft: Application to microburst downdraft. *Journal of the Atmospheric Sciences* 42, 1004–1023.

Figure 5 Comparison of the axial profiles for cooling owing to phase changes of condensate for the dry microburst with snow and the wet microburst with hail. Location of the melting level based on the environmental sounding is shown. Reproduced from the American Meteorological Society from Proctor, F.H., 1989. Numerical simulations of an isolated microburst. Part II: Sensitivity experiments. *Journal of the Atmospheric Sciences* 46, 2143–2165.

The sensitivity of the dry microburst to the microphysics of the condensate has also been shown. Numerical studies initiated with different precipitation particles reveal that snowflakes produce downdraft speeds nearly twice as strong as those generated by hail. The sublimation process associated with snowflakes is important for three apparent reasons: (1) the numerous low-density snow particles readily sublimate, with much of the snow content depleted before melting into rain; (2) the latent heat of sublimation is greater than the latent heat of either evaporation or melting; and (3) the cooling from sublimation takes place at a relatively high altitude within the deep adiabatic layer, allowing the downdraft to accelerate through a deep column.

High-Reflectivity or Wet Microburst

In more stable lapse rates, the downdraft tends to be warmer than the environment. In such a case, the drag of the condensed water may become important in accelerating the downdraft, especially at high levels. Accordingly, higher rainwater mixing ratios (i.e., radar reflectivities) are required for microbursts to form. This effect is well illustrated in Figure 4. The few microbursts that occurred for lapse rates less than $\sim 8.0 \text{ K km}^{-1}$ were associated with radar reflectivities in excess of 45 dBZ, suggesting that higher water contents are needed to produce strong downdrafts. This often manifests itself in radar reflectivity images as a prominent descending precipitation core. It has been shown that melting also plays an important role in producing a wet microburst. Narrow shafts of hail, coincident

with the microburst downdraft, embedded within a heavy shower of large raindrops have been noted.

The comparison of wet and dry microburst simulations is shown in Figure 5. The dry and wet microbursts were driven by snow and hail, respectively. Note that the temperature deviations for the two cases are different. The dry microburst is associated with smaller cooling, but it occurs through a deep column. The temperature deviation for the wet microburst is largest at the ground but diminishes rapidly with height until it becomes warmer than the ambient air above 1 km. The warming aloft for the hail case indicates the importance of precipitation loading in the early stages of the wet microburst which overcomes the positive buoyancy. It is hypothesized that hail produces stronger microbursts in more stable environments, since the downdraft is maintained only at lower elevations where it is less likely to be depleted of negative buoyancy because of compressional heating. Note that strong negative buoyancy is confined to the lowest levels of the wet microburst in Figure 5. The dominance of negative thermal buoyancy near the ground combined with the decreasing effect of precipitation loading can result in a displacement between the location of the strongest downdraft velocities and the maximum in radar reflectivity.

An important observation was revealed in the simulations shown in Figure 5. Although the downdraft associated with the dry microburst was much deeper and almost twice as intense as that of the wet microburst, both produced identical outflow speeds. This points to the immense difficulty in estimating peak outflow speeds based on the expected downdraft velocities. The cold air for the wet microburst is situated primarily at low levels in Figure 5. Although this cooling near the ground is not able to translate into strong enhancement of the downdraft, it may strengthen the outflow speeds through enhanced horizontal pressure gradient forces produced by the formation of a mesohigh. Dry microbursts are typically accompanied by small, cold pools (i.e., weak mesohighs). Thus, strong outflow winds for the dry microburst are possible only when the downdraft speeds are also intense. This comparison of these two cases emphasizes the nonlinear relationship between vertical velocities and outflow speeds.

Forecasting and Detection

Although intense microbursts are often associated with the supercell storm, most microbursts develop within environments characterized by weak vertical wind shear. The thermodynamic profile determined by nearby upper-air soundings is particularly useful for identifying when strong, convectively induced winds are likely to form. The two types of profiles that have been associated with strong outflow are the 'inverted V' profile conducive to dry or low-reflectivity microbursts and the weakly capped wet or high-reflectivity microburst. The former is shown in Figure 6. Its main characteristics are the deep, dry adiabatic, subcloud layer from near the surface to the mid-levels, a dry lower layer, and a moist midtropospheric layer. The convective instability is small or marginal, therefore the convection is often weak. The latter characteristic is consistent with numerous observations of dry microbursts associated with virga shafts pendant from innocuous clouds. Forecasting schemes are usually based on the 1200 UTC sounding and expectations for solar heating and maximum surface temperatures later in the day.

Figure 6 Schematic of the characteristics of the thermodynamic profile of the morning and evening soundings favorable for dry microburst activity over the high plains. Reproduced from the American Meteorological Society from Wakimoto, R.M., 1985. Forecasting dry microburst activity over the high plains. *Monthly Weather Review* 113, 1131–1143.

Figure 7 Thermodynamic model summarizing the environment conducive for wet microburst occurrence. Reproduced from the American Meteorological Society from Atkins, N.T., Wakimoto, R.M., 1991. Wet microburst activity over the southeastern United States. *Weather and Forecasting* 6, 470–482.

Wet microburst profiles typically display high moisture values through a deep, surface-based layer, with the top of the moist layer sometimes extending beyond 4–5 km AGL. Relative humidities above the moist layer are low. The dry adiabatic subcloud layer may only be 1.5 km deep and the capping inversion is weak. It has been suggested that the vertical profile of equivalent potential temperature can be useful in identifying environmental conditions capable of supporting wet microbursts (Figure 7). The difference in the equivalent potential temperature between the surface and midlevels equal to or greater than 20 °C appears to be a characteristic profile during wet microburst events. In addition to the morning sounding, predicted moisture and thermal advection patterns must be taken into consideration.

Microburst detection in real time has focused on the use of single-Doppler radar. A number of radar signatures have been identified that occur typically 2–6 min prior to the initial surface outflow. Descending reflectivity cores, increasing radial convergence within the cloud (in response to an accelerating downdraft), intense small-scale circulations, and weak echo reflectivity notches (in response to entrainment of low equivalent potential temperature air) have all been found to be important microburst precursors.

Basic research on microbursts has been quickly and successfully transferred into the operational community. Many of the airports around the United States have now implemented systems that provide timely warning to air traffic controllers and pilots of impending wind shear events associated with microbursts.

Severe Storms

CA Doswell III, University of Oklahoma, Norman, OK, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The concept of a severe storm is defined, because there are many different types of weather that can be called a 'storm' and the severity of a storm is measured by the intensity of the weather produced. It is generally the case that as the scale of a storm decreases, its intensity increases, but it affects a smaller area and does not last as long as a larger scale storm. Storms roughly the size of a continent (several thousand kilometers across) are called 'synoptic-scale' storms. When the size of a storm is roughly the size of a few hundred kilometers across, it is called a 'mesoscale' storm. Severe thunderstorm systems can be considered mesoscale, but the individual storms are a few tens of kilometers across. Severe storms in the tropics form a special class of their own. Property and casualty mitigation from severe storm events is discussed.

Introduction

The word 'storm' implies a disturbance of some sort in the weather, but many different types of weather can result in an event called a 'storm.' Thus, it is possible to have windstorms, dust storms (which also are windstorms), hailstorms, thunderstorms, winter storms, tropical storms, and so on. Generally speaking, events called 'storms' are associated with cyclones; undisturbed weather is usually found with anticyclones.

Similarly, the meaning of severity needs to be considered. The *intensity* of the event in question is often the basis for deciding on the severity of that particular storm. However, if storm intensity is to be our basis for categorizing a storm as severe, then we have to decide what *measure* we are going to use for intensity. This also usually implies an arbitrary threshold for deciding the issue of severity. That is, weather events of a given type are going to be called severe when some measure of that event's intensity meets or exceeds a threshold, which can be more or less arbitrary. A hailstorm might be severe when the hailstone diameters reach 2.5 cm or larger, a winter snowstorm might be called severe when the snowfall rate equals or exceeds 5 cm h⁻¹. On the other hand, some storms of *any* intensity might be considered severe. A tornado is a 'storm' embedded within a thunderstorm; tornado of any intensity is considered a severe storm.

The difficulty with *arbitrary* definitions is that they imply a change in character whenever the threshold criterion is met. That is, if a hailstorm produces hailstones of 2.4 cm in diameter, a threshold of 2.5 cm means that such a storm is not severe. However, from most anyone's viewpoint, is it reasonable to try to distinguish between a storm producing 2.4 cm diameter hailstones from one producing 2.5 cm hailstones? In the majority of cases within the science of meteorology, there is no obvious way to distinguish events with this sort of precision. A small *quantitative* change in some intensity measurement is not necessarily associated with a *qualitative* change in the character of a storm. It is near the threshold (wherever that threshold is chosen) that it becomes challenging to analyze and predict storm 'severity.' This will be elaborated on in dealing with the specific events described below. However, the

challenge of *defining* severity should be kept in mind in the following discussion, as we consider various types of severe storms.

Severe Midlatitude Storms

The Tropics are defined formally as lying equatorward of 23.26° latitude in the Northern and Southern Hemispheres: the 'Tropics' of Cancer and Capricorn, respectively. Poleward of these latitudes and equatorward of 60° latitude lie the so-called midlatitudes. There are important distinctions between the weather of midlatitudes and that of the Tropics. Notably, in midlatitudes, the Coriolis force is a dominant part of the meteorology, whereas in the Tropics, its impact on the large-scale weather is of lesser importance, with some notable exceptions, including tropical cyclones.

Synoptic-Scale Storms

Cyclones in midlatitudes that are thousands of kilometers in horizontal extent are known as *synoptic-scale* systems. These are the familiar rotating weather systems (Figure 1) shown routinely in newspapers and on television. Such storms serve an important function in the global circulation, helping to carry warm air poleward from the tropics and cold air from the polar regions equatorward. This process keeps the imbalance of solar heating from creating an extremely strong temperature contrast between the poles and the equator. In association with these synoptic-scale cyclones, intense temperature contrasts can develop (Figure 2), called *fronts*, which are the leading edges of the cold air flowing equatorward and warm air flowing poleward. These midlatitude cyclones are part of the normal progression of weather systems, typically bringing clouds and precipitation with them.

In some situations, where the hemispheric weather patterns have become slow moving, these cyclones can result in prolonged periods of heat or cold in some regions. When extreme temperatures (hot or cold) are reached, these can be hazardous to humans for a variety of reasons, but would not generally be considered 'storms' despite that.

Figure 1 False color-enhanced satellite image of a synoptic-scale cyclone on the afternoon of 10 November 1998, showing the center of the cyclone near the spiral of clouds in southeastern Minnesota. This cyclone was producing severe thunderstorms in and near the Gulf of Mexico, as well as snow and high winds on the northern plains, in North and South Dakota. NOAA image.

Figure 2 Map of surface temperatures at about the same time as **Figure 1**, showing the strong contrast in temperatures along the cold front, with subfreezing temperatures in North and South Dakota at the same time that quite warm temperatures are present over the Gulf of Mexico. Many subsynoptic-scale features can also be seen in mountainous regions; for example, in the Appalachian and Rocky mountains. Image courtesy of National Center for Atmospheric Research.

Synoptic-scale cyclones sometimes become particularly intense, and the pressures at their cores can become quite low, in comparison to the average. In such cases, during the process of intensification, pressures can fall quite rapidly as the result of the dynamic processes operating to cause the intensification. Cyclones with fast-falling pressures are sometimes called 'bombs' and, whereas they can be considered storms in their own right, these synoptic-scale cyclones may be responsible for several different types of stormy weather within them.

Rapidly falling pressures create strong winds over a wide region. Winds and heavy precipitation resulting from synoptic-scale cyclones can produce considerable damage and associated casualties; recent examples occurred in France during December 1999 and along the east coast of the United States in January 2000 and March 1993 (the so-called Superstorm of 1993). Another well-publicized example hit the United Kingdom in October 1987. Damaging winds can extend over many hundreds of kilometers and last in any one place for a full day or more. The result of such widespread damaging wind can be overwhelming to emergency services, and power outages alone can last for days in some places simply because of the sheer size of the affected area. At sea, strong winds from intense synoptic-scale cyclones also produce large waves that represent hazards to ships of all sorts. The winds from intense cyclones at sea can cause serious damage, including beach erosion, when they affect coastal areas.

In addition, intense synoptic-scale cyclones can produce a full spectrum of hazardous precipitation. Such storms can occur at any time of the year but are most common from autumn through spring, and so the cyclones are capable of paralyzing snowstorms, ice storms, heavy rainstorms, and even severe thunderstorms. Accumulations of ice and snow during winter storms of this type are potentially hazardous to ships and aircraft.

Depending on the circumstances, two or more of these different severe weather types could be happening at the same time, in different places. A given location might experience all of them in the course of a single day during the passage of a synoptic-scale cyclone. In other situations, only one form of severe weather occurs within such a cyclone.

Synoptic-scale cyclones are important in creating the conditions for the development of smaller scale storms. It is a general principle in meteorology that as the size of a weather system decreases, the maximum intensity of the weather it can create increases. Although synoptic-scale systems certainly can produce widespread damage, it is usually not of the most extreme intensity. However, the conditions within such storms can result in smaller concentrations of severe weather that become even more potentially hazardous.

Mesoscale Storms

Mesoscale weather is in the range of hundreds of kilometers, whereas synoptic-scale weather happens on scales of several thousand kilometers. Synoptic-scale weather processes go on essentially all the time (although the really intense events are generally rare), whereas mesoscale storms are intermittent. That is, they arise only occasionally in any given location and then only when the conditions for their formation are produced by the processes operating on the synoptic scale. There are two

general classes of mesoscale storm systems: those that arise from interactions between the atmosphere and the underlying surface, and those that occur even in regions of relatively uniform conditions at the surface.

Those systems that depend on the underlying surface cover a wide range of phenomena. There are many atmospheric circulations, like land-sea breezes that are more or less routine, driven by the underlying topographic conditions and occurring on most days of the year; in the case of the land-sea breeze, it is the temperature contrast between the land and the sea that drives the flow. During the day, the land is warmer and air tends to rise over land, to be replaced by cooler air flowing in from the sea. At night, the opposite happens. Of course, most of these circulations would not be considered 'storms' in the sense that we have been using. However, such processes as land-sea breezes can be influential in the *development* of stormy weather, often in the form of thunderstorms that are initiated along them.

Occasionally, the circumstances produced by the synoptic-scale flow as it interacts with the surface result in stormy conditions. A common example is when the airflow interacts with complex terrain, producing localized windstorms. There are examples of these mesoscale windstorms around the world, often given colorful names. Mesoscale windstorms such as the Chinook (in Alaska), the Foehn (in the European Alps), the Tramontana (in the western Mediterranean), the Bora (in the Adriatic), and so forth have been recognized as important weather events for centuries. Windstorms in complex terrain arise in different circumstances; they are not all driven by the same mechanism. Some are simply cases where cool, stable air is being funneled through gaps in the terrain (e.g., the Tramontana); others develop when strong winds aloft are brought down to the surface by processes induced by airflow over the mountains (as in Boulder, Colorado). The situation creating the windstorms is created by the synoptic-scale flow, but the strongest winds are confined to a mesoscale area.

Another class of mesoscale storms can arise when cold air flows over relatively warm waters. Certain storms of this sort, called 'polar lows,' apparently arise through processes not unlike those of tropical cyclones, drawing energy from the ocean to develop their intense circulations. They occur when outbreaks of very cold polar air flows over relatively warm waters. Given their mesoscale size, they often are characterized by intense pressure gradients, leading to the occurrence of strong windstorms. Their size means the weather they bring may only last for part of a day, but during the passage of the storm, winds can meet, and even exceed, the hurricane threshold: 33.5 m s^{-1} . The windstorms associated with polar lows can be quite hazardous, especially when they occur in association with low temperatures (resulting in severe wind-chill conditions). In addition, polar lows can produce blinding snowstorms with snowfall rates of perhaps 200 mm h^{-1} , leading to extremely dangerous blizzard conditions. On some occasions, they can be associated with strong and possibly severe thunderstorms, as well.

When cold air has a long fetch over the relatively warm waters of large lakes early in the cold season, yet another type of mesoscale storm can arise: the lake-effect snowstorm. The orientation of the synoptic flow determines when and where

Figure 3 An example of a polar low in the cold airstream behind a wintertime synoptic-scale cold front associated with a synoptic-scale cyclone (a low-pressure center). NOAA image.

lake-effect storms develop. These snowstorms can produce sustained heavy snowfall rates, resulting in deep snow accumulations in preferred locations and sometimes are accompanied by thunder and even waterspouts.

Even when the underlying surface is more or less uniform, mesoscale storms can develop *within* synoptic-scale cyclones (Figure 3). These usually are tied to a mesoscale disturbance in the middle or upper troposphere that encounters conditions favorable for its intensification. Such systems can produce unforeseen snow and ice storms in the winter, and severe thunderstorms during the warm season. There may not be a strong cyclone near the surface in such events.

Severe Thunderstorms

Severe thunderstorms typically produce weather events that cover a wide range of size scales, from a few hundred kilometers down to just a few kilometers, or even smaller. This is because thunderstorms can occur as isolated events or in groups. In the United States, a thunderstorm-related event is considered severe when the wind gusts equal or exceed 25 m s^{-1} , or the hailstone diameters exceed 2.5 cm, or if a tornado is produced. As noted earlier, these criteria are mostly arbitrary.

A thunderstorm is composed of one or more cells, where a *cell* is the basic building block of a thunderstorm. Cells, in turn, are made up of one group of air parcels being driven upward by positive buoyancy and another being driven downward by negative buoyancy and the presence of precipitation in the air. Positive buoyancy arises in updrafts by the release of latent heat during the condensation of water vapor.

This heat release acts like the burner of a hot air balloon, reducing the density of the air in which condensation is occurring and thereby causing the air to rise. As the process continues, under the right conditions, precipitation forms in the updraft. This precipitation can produce downdrafts simply by its accumulating weight dragging downward on the surrounding air. Moreover, when precipitation falls into relatively dry air surrounding a developing storm, the evaporation of that precipitation chills the air; evaporation absorbs latent heat from the air in the same way that condensation releases that heat.

When downdrafts caused by thunderstorms reach the surface, they are forced to spread out, like pancake batter poured onto a griddle. This creates an outflow at the surface (sometimes called a *downburst*), with the outflow winds sometimes reaching the criterion for calling the thunderstorm severe. On some occasions, these outflow winds can exceed 40 m s^{-1} .

For particularly strong updrafts, the possibility of large hail formation arises. Hailstones develop in the part of the storm where supercooled water and ice crystals are both present; liquid water is said to be supercooled when its temperature is below the melting point (0°C) and the water is not yet frozen. Hailstones can become quite large, exceeding 5 cm diameters at times, and be capable of penetrating roofs, shattering windows, and occasionally creating human casualties. Even small hail can cause crop damage, of course.

In general, tornadoes form in association with severe thunderstorms. Tornadoes are intense low-pressure vortices that can produce the strongest winds of any storm; at their highest intensity, tornadic wind speeds can approach 140 m s^{-1} . Most tornadoes, however, are not that intense.

Tornadoes over bodies of water are called *waterspouts*, but there is no scientific distinction between them. Tornadoes are created in thunderstorms when pretornadic, relatively weak circulations are intensified through conservation of angular momentum.

Isolated Events

The most intense form of thunderstorm is the so-called *supercell* thunderstorm, which typically is isolated from surrounding storms. Supercells are rotating thunderstorms that develop their rotation by drawing upon the vertical wind shear in the prestorm environment. The vast majority of supercells produce some sort of severe weather: hail, damaging straight-line winds, and/or tornadoes; only about 20% of them are tornadic, however. The most violent severe weather of all types is almost always associated with supercells (Figure 4), including the majority of strong and violent (F2–F5 on the Fujita scale) tornadoes and giant hailstones (exceeding 5 cm in diameter).

Whereas the typical thunderstorm cell has a lifetime of about 20–30 min, supercells can persist for many hours. This means that all forms of severe weather from supercells can be prolonged, sometimes leaving long, wide swaths of damage (see Figure 5). The organized nature of a supercell, associated with its overall rotation, means that supercells produce a disproportionate share of the damage associated with thunderstorms. Perhaps only about 10% of all thunderstorms are supercells, but they are responsible for the majority of thunderstorm damage in areas where they occur.

Because supercell updrafts are often intense, supercells can become prolific hail producers; a noteworthy example was a supercell that hit the Dallas–Fort Worth Metroplex on the evening of 5 May 1995 with softball-sized hail and torrential rains. The damage from that one storm was estimated at \$1 billion and there were numerous hail-related injuries.

Apart from supercells, isolated thunderstorms usually are nonsevere and typically do not last very long. On rare occasions,

isolated thunderstorms can produce a brief ‘pulse’ of severe weather, usually hail or winds that are only marginally severe.

Aggregations of Thunderstorms

Thunderstorms do not always occur as isolated events. Rather, they tend to form in groups, in either lines or clusters of individual cells. The most common grouping is in lines, sometimes referred to as *squall lines*. When thunderstorm cells form in aggregations, then the collection of storms can live for a much longer time than the individual cells (which retain their 20- to 30-min lifetimes). This means that the hail and wind events produced by such groupings of thunderstorms are intermittent, rather than prolonged (as with supercells), as cells form and decay within the group. Severe weather still can go on in such cases for many hours in this intermittent fashion. The interactions between individual cells in lines and clusters of thunderstorm cells are often complicated and hard to predict, but those interactions can also be responsible for severe weather.

A particularly dangerous form of thunderstorm aggregation arises when new cells are constantly forming in one place, and tracking over the same region repeatedly, a situation called ‘training’ because the cells are like cars in a train. This means that a particular area experiences rainfall from a succession of thunderstorm cells, which can result in extremely heavy rainfall. This is the process associated with the majority of flash flood events, worldwide. In the United States, heavy rainfall is not considered to be a criterion for what is officially considered to be ‘severe’ in spite of the importance of such rainfall in flooding events. On the other hand, many other nations around the world consider heavy rainfall to be an important form of severe storm.

Severe Tropical Storms

The most obvious severe weather associated with the tropics are *tropical cyclones*. These storms are known by different

Figure 4 Supercell-associated tornado on 9 June 2005, near Zurich, Kansas. Image © 2005 C. Doswell (used by permission).

Figure 5 Map of supercell tracks associated with the outbreak of severe storms and tornadoes on 27 April 2011, over the southeastern United States. NOAA image.

names in different parts of the world: hurricanes (in North America), typhoons (in the tropical Pacific), and cyclones (in the Indian Ocean and Australia), among others. However, they all are the same phenomenon. Such storms arise when sea surface temperatures become warm, the vertical wind shear is weak, and tropical weather disturbances move through the easterly trade winds of the Tropics. They produce winds in excess of 33.5 m s^{-1} and the peak sustained winds (i.e., not gusts) can approach 90 m s^{-1} in extreme cases. The size of the region of damaging winds can vary considerably from one event to another, but winds exceeding 'hurricane force' (33.5 m s^{-1}) can be found within a circle on the order of 100 km or so in diameter. Such a large region of strong winds means that damaging wind speeds can go on for many hours.

Although they are well known for strong winds, tropical cyclones can pack a lethal combination of hazards: storm surge, heavy rainfalls, and even embedded tornadoes, as well as the more well-known strong winds. Storm surge is created by a combination of strong winds and low pressure, resulting in an elevated sea level near the center of the storm. When this surge, which can be several meters high, makes landfall, low-lying coastal regions can be inundated. The rainfall component is nothing to take lightly, either. Hurricane Mitch (Figure 6) devastated parts of Nicaragua and Honduras in 1998, mostly from flash floods and landslides. There were more than 9000 fatalities, making it the worst weather disaster in the twentieth century in the Western Hemisphere.

Tropical cyclones are usually several hundred kilometers in diameter and can last for tens of days. Their paths often

take them out of the Tropics into midlatitudes, where they can maintain their structure for a time before eventually dissipating or transforming into midlatitude cyclones. Tropical storms usually dissipate shortly after making landfall, because their energy source (warm seawater) is cut off. Nevertheless, dissipated tropical cyclonic storms can remain dangerous well after they lose their strong winds by creating an environment favorable for heavy rain-producing thunderstorms.

Relatively little is known about other types of severe storms in the Tropics. Severe thunderstorms, especially supercells, are uncommon in the Tropics because of a general lack of vertical wind shear. Of course, heavy rain-producing tropical thunderstorms are relatively common in some parts of the Tropics.

Societal Impacts and Their Mitigation

Severe storms in all their variety cause the loss of hundreds of lives and several billion dollars in property during the course of a year in the United States. It is worth noting that the United States can recover from such property damage because of its large, generally healthy economy. Severe storm economic losses in the United States typically are much less than 1% of the gross domestic product (currently several trillion dollars), so by spreading out the impact of severe storms, the areas affected can recover and rebuild. On the other hand, when severe storms (e.g., Hurricane Mitch) devastate less-developed nations with small economies, the damage to their infrastructure can be so large that it might take decades to recover.

Figure 6 View from the GOES-8 geostationary satellite of Hurricane Mitch near Honduras and Nicaragua. NOAA image.

Forecasting severe storms has shown a slow increase in accuracy during the past several decades, as new technologies are leading to improved understanding and predictability. The accuracy of forecasts generally increases as the scale of the storm increases; it is possible to be more accurate with a synoptic-scale forecast than with a forecast on the scale of a single thunderstorm in most cases. There is more complete understanding of the synoptic-scale meteorology than on scales smaller than synoptic. Furthermore, forecast accuracy generally decreases with the age of the forecast, at a rate that also depends on the scale. The accuracy of a synoptic-scale forecast can stay high for a few days, whereas a forecast of a thunderstorm-scale event can remain accurate for a few tens of minutes, at most.

Property damage mitigation depends mostly on making the right preparations for the storms that are possible in a given location, well in advance of the storms. Once the storms are underway, there tends to be relatively little that can be done to prevent property damage. For example, a home built on a barrier island that can be swept by landfalling tropical cyclones is unlikely to remain undamaged for more than a few decades, at most. As the storm approaches, there is little time to do anything substantial to the home to limit structural damage. Any damage mitigation would be of a superficial nature, such as boarding up the windows. Thus, structural damage can be prevented primarily by not building in vulnerable areas. On the other hand, there are several ways in which homes can be constructed to resist tornado damage (Figure 7), unless the homeowner is unlucky enough to be hit by the most intense winds in a violent tornado. Within the damage swath produced by a violent tornado, only a few places will actually experience the most violent winds; most of the rest of the structures will encounter winds that can be resisted through appropriate construction practices.

Casualty mitigation can be a complex topic, as well. In some instances, as with tropical cyclones, evacuation is possible and

Figure 7 Damage caused by a violent tornado that hit the city of Moore, Oklahoma, on 3 May 1999. FEMA image.

may be the best way to protect lives when it is feasible. For tornadoes, having access to a suitable shelter is preferred; in situations where proper shelter is not available, the alternatives during tornadoes are not very good. For flooding situations, evacuation to higher ground is the appropriate way to prevent casualties, when time permits.

The ability to detect and predict severe storms is also important for casualty mitigation. In the United States, there has been a gradual reduction in weather-related fatalities with time, in part because there are fewer 'surprise' storms today, and in part because education about severe storm hazards has led to improved public preparations. Nevertheless, we continue to be vulnerable as a nation to disasters caused by severe storms, and complacency can be a fatal error.

Introduction

What is a waterspout? It is defined as an intense columnar vortex (usually containing a funnel cloud) of small horizontal extent that occurs over a body of water and is suspended from a cumuliform cloud.

Waterspouts occur most frequently in the subtropics during the warm season; more are reported in the Florida Keys than in any other place in the world. Funnel diameters range from a few up to 100 m or more, lifetimes average 5–10 min, but large waterspouts may persist for up to 1 h and are the most hazardous. Examples of typical and large Florida Keys waterspouts are shown in Figures 1 and 2. Waterspouts can also occur in groups or sequential families of up to nine from a single cumulus cloudline over a 90 min period, as shown in Figure 3.

Figure 1 'Typical' waterspout, photographed by the author from light aircraft, west of Key West, FL, on 9 July 1969.

Worldwide Climatology

Literature on waterspouts is virtually nonexistent. By far, the majority of the work on this subject comprises individual observations of waterspout occurrence from the surface, a few documented by still photographs or drawings constructed from memory. Perhaps one of the best early comprehensive surveys of waterspout structure and behavior, deduced from observations available up to that time, was made by Ferrel in his *A Popular Treatise on the Winds*. Up to the late 1960s, there remained much disagreement over certain structural features of the waterspout, especially the sense of vertical motion in and surrounding the funnel. Vortex structure within the parent cloud remains virtually unknown. Some of the more plausible waterspout models deduced from surface observations have been proposed by Bundgaard, Dinwiddie, and Rossman. These

Figure 2 Large waterspout, photographed by the author during a chance aerial encounter near Lower Matecumbe Key, FL, on 2 September 1967. Note the double-walled structure of the funnel cloud, with spray vortex and trailing wake on sea surface.

Figure 3 Schematic, composite scaled model of a waterspout-active cloudline, illustrating typical locations of waterspouts in various stages of life cycle (to be outlined later), motion relative to shower locations, and mesoscale flow (plan view above, side view below).

Figure 4 Waterspout model derived by Dinwiddie, 1959.

are depicted in **Figures 4–6** and illustrate some of the contrasting models of waterspout structure and radial-vertical circulation up to the 1960s. The only estimate of the pressure minimum in a waterspout was given by Chollet. He described a ship being overtaken by a waterspout during which the ship's barometer fell 21 hPa.

Gordon assembled a global waterspout frequency map, using British ship observations from 1900 to 1947. Apart from the observational bias of using only British ships and their selective routes, we note that more waterspouts occur on the western sides of the subtropical anticyclones. This distribution implies that waterspouts are most frequent in the equatorial Atlantic and Indian Oceans, the Gulf of Mexico, and the Mediterranean Sea. Gordon concluded from his data that

Figure 5 Schematic waterspout flow model from the frame of a 16 mm movie taken of a 1953 Tampa Bay waterspout by Bundgaard, 1953.

Figure 6 Rossman's, 1960 waterspout conceptual model: 'Streamline divergence at the base of a waterspout and shape of the sea surface... gives schematically the flow pattern of a waterspout foot: a depression in the water surface or a ringshaped wave, the crest of which breaks up in water droplets and forms the spray around the funnel'.

waterspouts occur generally over regions having relatively high sea and air temperatures for the latitude, where consequent unstable conditions are likely to exist in low levels.

Gordon's frequency chart illustrates that waterspouts rarely occur along the western coasts of North and South America, Europe, and Africa where cold upwelling in the ocean is common.

United States Waterspout Climatology

More recently, the author performed an assessment of waterspout frequencies along the US East and Gulf Coasts. Two primary data sources were utilized in the compilation of this waterspout climatology. All NOAA *Storm Data* reports from coastal counties during the period 1959–73 were examined for waterspouts, tornadoes, and funnel clouds. Tornadoes that passed over coastal lakes or waterways, or crossed a coastline and continued out to sea were included in the waterspout

Figure 7 Waterspout climatology for US Gulf and Florida Coasts (*NOAA Storm Data*: 1953–73; ship reports: 1850–1940). Different boxed coastal regions were chosen to correspond to major population centers and geographical boundaries. The upper number refers to total waterspouts (see text) and the lower number to damaging cases. ‘Several’ implies more than 10 waterspouts.

statistics and plots. Funnel clouds that were likewise reported over water bodies were also included as probable waterspouts, using the research results by the author on the waterspout life cycle as a guide. The second data source was a large file of mariners’ reports covering almost a century, 1850–1940, for the entire western North Atlantic and Gulf of Mexico. This file was kept by past editors of the *Mariner’s Weather Log*, and is therefore probably biased toward United States vessel reports. The results for waterspout totals and damaging waterspouts for demographically partitioned areas are plotted in **Figure 7** for the US Gulf and Florida coasts, and similar results are given by the author for the US East Coast north of Jacksonville. (Waterspout statistics for the Florida Keys have been omitted from **Figure 7**, but are given below for the years 1958–68.) As noted in the Introduction, over 30 years of research has shown that waterspouts occur more frequently in the Florida Keys than anywhere else in the world. Moreover, Golden (1973) demonstrated that conventional data sources for the Keys underestimate the actual yearly waterspout population by up to an order of magnitude. This tendency is likely present in the *Storm Data* used for the Gulf and East Coasts; public apathy and lack of understanding about potential waterspout hazards are contributing factors. **Figure 7** and other similar waterspout charts of the East Coast show that the primary warm axis of the Gulf Stream and large coastal bays and inland waterways are favored regions of waterspout occurrence. More recent studies show increasing reports of waterspouts along the Southern

California coast and Great Lakes (Buffalo and Cleveland), both partly due to increased public awareness. Rare outbreaks of waterspouts have been documented in such odd northern locations as Lake Winnipeg (Canada), the Great Salt Lake (UT), Lake Tahoe (NV), and Baseline Reservoir (Boulder, CO).

Table 1 gives a list of the 10 most active areas along the entire US Gulf and East Coasts in decreasing order of reported waterspout frequency for the 15 year period. The Florida Keys experience from 50 to 500 waterspouts *each year* (at least 400 waterspouts were documented during the 1969 Lower Keys Waterspout Project). Total waterspouts and the number producing damage are given for each coastal area. Tampa Bay has the greatest number of damaging waterspouts and it is known that half or more of these originate over the Gulf of Mexico during midlatitude disturbances.

Annual/Seasonal/Diurnal Waterspout Frequencies in the Florida Keys

According to Gerrish and to 1969 data studied by Clemons, nearly all vortices reported as funnel clouds over water actually are weak waterspouts, and this has been confirmed by the present author’s research. **Figure 8** shows the annual totals of funnels and funnel-days from 1958 to 1968 for Key West Weather Service Office observations. A ‘funnel-day’ is defined as a day when one or more funnels were sighted. Note that

Table 1 Top 10 coastal areas for waterspout occurrence: US East and Gulf Coasts, 1959–73 (all values are 15 year totals)

Location ^a (areal coverage)	Total spouts	Spouts per unit area ($\times 10^{-4} \text{ km}^{-2}$)	Damaging cases
1. Florida Keys ^b (22 809 km ²)	> 1000	> 6572	15
2. Greater Miami, FL (10 138 km ²)	335 (++)	330	16
3. Tampa Bay, FL (6970 km ²)	235 (++++)	363	33
4. Palm Beach, FL (5069 km ²)	234	462	7
5. Corpus Christi, TX (6246 km ²)	211 (+++++)	338	≥ 10
6. Ft Lauderdale-Del Rey Beach, FL (5069 km ²)	180 (++)	355	10
7. Galveston Bay, TX (11 560 km ²)	161 (+++++)	139	12
8. Mississippi River Delta ^c , N Orleans (South of Lake Maurepas to Mississippi Delta) (14 790 km ²)	142 (++)	96	12
9. Pensacola Bay, FL (4164 km ²)	110 (+)	264	13
10a. Ft Myers, FL (12 672 km ²)	104	82	12
10b. Mississippi Sound, MI (5651 km ²)	103 (++)	182	16
10c. Port Arthur, TX, to Sabine Lake (5711 km ²)	102 (+)	179	10

^aCompare these data with [Figures 1 and 4](#).^bEstimated from field data in Golden (1973) and Rossow (1970).^cLake Pontchartrain, north of New Orleans, had 96 (+++++) total waterspout reports, one damaging (*not* included here).

Note: Each + indicates one observation of several or numerous waterspouts and was counted as only one event in the tabulations.

**Figure 8** Number frequency of funnel clouds and funnel-days per year (1958–68) from the Key West, FL, National Weather Service, NOAA data. Adapted with permission from Clemons, 1969.**Figure 9** Funnel days per month for the period 1958–68 (dashed) and for 1969 (bottom, solid) from Key West NWS data. The top solid line is the mean monthly sea surface temperatures at Key West pier during 1958–68.**Figure 10** Number of funnel clouds per month for the period 1958–68 (dashed) and for 1969 (solid) from Key West data. Note the double peak in each curve and the distinct minimum in July.

there were 35 funnel-days reported by Weather Service observers during 1968. However, including data from other sources in the Lower Keys, the number swells to 56 funnel-days observed within 30 km of Key West for the period. Lower Keys funnel sightings during 1968 far exceeded the annual frequency for the previous nine years.

Waterspouts in the Lower Keys are primarily a rainy-season phenomenon (May to October). The dashed curve ([Figure 9](#)) shows the number of funneledays per month at Key West (1958–68). June is the most active waterspout month, in terms

Figure 11 Diurnal trends in total number of funnels observed each hour (EST) during 1969 (solid) and 1958–68 (dashed); funnel observations from research aircraft are for 1969 (dotted).

Figure 12 Large tornadic waterspout accidentally photographed by time exposure near midnight, looking east from a balcony at N Miami Beach, 15 June 1985. © Jim Leonard, used with permission.

of funneldays, closely followed by August and July, with May, September, and October substantially less active. Note the in-phase relationship between trends in funneldays per month and monthly mean ocean water temperature at Key West. **Figure 10** (dashed curve) shows the 11 year funnel cloud totals plotted by month. From April to May, the total funnel number increases from a few to 50 and then nearly doubles from May to June (the secondary maximum).

Diurnal Occurrence and Duration

The diurnal distribution of waterspout funnels (1958–68) is given by the dashed curve in **Figure 11**. There are two primary maxima: the first near the noon hour (1130–1300 EST) with a slight decrease near 1330 EST, and the second maximum from 1630 to 1830 EST. A lower tertiary peak occurs in the early

Figure 13 Temperature sounding taken from an outside-dial temperature gauge on light aircraft (read to the nearest 0.5°C) beneath a waterspout-active cloudline on 7 July 1969. Key West, FL, sounding at 1200 GMT is also plotted for comparison (9 h earlier and approximately 20 km from cloudline).

Figure 14 Mature waterspout with intense spray vortex, being chased by a large speedboat towing a water-skier, over shallow waters west of Key West, FL, in June 1977.

Figure 15 Proposed three-dimensional structural model of a waterspout based on detailed aircraft observations of the Lower Matecumbe Key waterspouts at close range. The vertical scale is greatly contracted. The inset shows the derived radial profile of tangential speeds through the waterspout's spray vortex, obtained by photogrammetric analysis of aircraft movies. Note the trailing 'wake' of disturbed sea water, with the wave train oriented perpendicular to and on the right side of the wake (cyclonic waterspout). See text for additional details.

morning between 0800 and 0900 EST. A few nocturnal waterspouts have been reported by Coast Guard and Navy pilots flying at low altitude and by Keys residents. A recent, extremely rare photograph of a large tornadic waterspout at around midnight is shown in Figure 12. This photograph was taken in time exposure from the balcony of a high-rise apartment in North Miami, looking east. The photographer was shooting lightning photographs and captured the large waterspout funnel and spray vortex by accident.

The average duration of funnel events (including both funnel clouds and waterspouts, 1958–67) was 14.6 min, which includes 61% of the total number; 1968 sightings averaged 13.0 min, which accounts for 66% of the total. For the 10 years 1958–67 and for the year 1968, 75% of the funnel events persisted for 20 min or less. The longest-lived funnel during the 1968 season lasted 52 min. Sixty-two minutes is the longest single event recorded (1958–67), but multiple funnel activity has been observed to last for almost 3 h from the ground.

Multiple Waterspout Events

Multiple-funnel sightings, with two or more occurring simultaneously, or more than one event on the same day, occurred on 54 of 167 funnel-days (1958–67) and on 14 of 35 funnel-days during 1968 alone. The maximum number of funnels sighted from the surface in Key West in a single day is eight (in June 1966 and August 1968). During one 45 min period of a 30 June 1969 flight, the author observed nine complete waterspouts emanating from the same cumulus cloudline. The maximum number sighted simultaneously from Key West (1958–68) is six; five have been reported several times.

Favored Weather Conditions for Waterspouts

A study was conducted using the above waterspout/funnel statistics with the NOAA Local Climatological Data for Key West, May to September, years 1964–68. High surface humidity and

Figure 16 Composite structural-flow model for the 'dark spot stage' of the waterspout life cycle. Compare with photographs in [Figure 21\(a\)–\(c\)](#). Characteristic range of scales is H (cloud base) = 550–670 m msl, D_f (maximum funnel diameter) = 3–45 m, and a = 15–760 m.

temperature (and therefore high equivalent potential temperature) favor funnel formation. For the period 1958–68, no funnels were reported when air temperatures were below 71°F or dew point below 66°F. Waterspouts may form in midlatitude locations such as the Southern California coast and the Great Lakes during the cool season with surface temperatures and dewpoints much lower than the Keys; however, in those situations other forcing mechanisms such as upper lows or approaching surface fronts play a major role. We examined a rare outbreak of several waterspouts, one of them large and tornadic, over Lake Tahoe in the early morning of 28 September 1998. Even though surface water temperatures on the lake were no higher than 70°F, the air mass was extremely unstable due to the presence of an upper cold low over Central California.

Prevailing wind direction during June at the surface in Key West is south-easterly, with a gradual backing to east-south-easterly in October, according to the *Climatic Atlas of the United States*. In May, the waterspout season onset month, prevailing surface winds are east-south-easterly. Wind speeds of $3\text{--}5\text{ m s}^{-1}$ were recorded during 57% of all funnel events, a calm was reported once, and 16 kn was the highest speed observed during funnel events. These wind speed figures exclude gustiness caused by showers. The two most frequent wind directions actually observed during funnel events are from 120° and 080° (1964–68). Conditions favorable for

Figure 17 Composite schematic model for the spiral pattern (stage 2) in the waterspout life cycle. The vertical scale is contracted, H (cloud base height) varies from 550 to 670 m msl, and d_s varies from 150 to 920 m. Bold arrows in spiral pattern indicate that a major band evolves around the dark spot during this stage. Compare with actual case photographs in [Figure 21\(c\) and \(d\)](#).

waterspout formation occur regularly on successive days in the summer months over the Florida Keys. Two or more successive funnel days were recorded for 20 of 167 occurrences during the 10 year period, but 10 were reported during the 35 funnel-days of 1968. Consecutive-day occurrences suggest some special slow-moving type of synoptic flow regime, and this hypothesis was examined and confirmed later by the author.

What, then, are the synoptic and mesoscale conditions associated with waterspouts? The synoptic scale was found to be the controlling influence on waterspout-active convective cloudline developments in the Lower Keys. If strong anticyclonic conditions persist in the 1000 to 600 hPa layer ($\sim$ lowest 4 km), subsidence will inhibit cumulus-cloudline development over the heated islands and shallow water. Additionally, if a strong cyclonic synoptic-scale disturbance (e.g. tropical storm) affects the Keys, the strong low-level winds and vertical wind shear will disrupt the surface heating mechanism. Whenever either several waterspouts or giant, long-lived waterspouts were observed, a weak but well-defined synoptic-scale troughline in the lower tropospheric mean flow approached and passed through the Keys, causing enhanced cumulus-cloudline development.

The cloudline scale (mesoscale) is perhaps most crucial to waterspout formation. It is estimated from the 1969–72 Keys waterspout data that at least 90% of the waterspouts are spawned by rapidly building cumulus cloudlines (i.e., not isolated cumuli). It is significant that spiral patterns usually form on the flanking edge of a cloudline, with the developing

Figure 18 Composite schematic model for the spray ring (stage 3) in the waterspout life cycle. The vertical scale is contracted, H varies from 550 to 670 m msl, and d_s from 445 to 260 m. See text for more details. Compare with the actual case in [Figure 21\(e\)](#).

rain shower or two generally within a few kilometers of the epicenter. Frequently, the tail or major 'feeder band' of the spiral appears to emanate from a narrow protrusion of the downwind shower boundary. These features are summarized in [Figure 3](#). Generally, there are both cyclonic shear and curvature in the low-level mesoscale flow through the cloudline. The updrafts and subcloud-layer convergence are enhanced by converging shower outflows, and the waterspouts move in the directions of these outflows. While most of the Keys' cloudlines are generated by the low-level differential heating mechanism from the chain of islands and large surrounding envelope of shallow, warm water, others are associated with preexisting mesoscale boundaries.

Typical 'waterspout proximity soundings' at NWS Key West show that the low-level winds are light ($5\text{--}8\text{ m s}^{-1}$) from a south-west-south-east-north-east direction (most often an easterly component), and veer with height up to 600–700 hPa. The vertical wind shear implied by these soundings is generally weak, but it may be locally enhanced by outflows generated by the cloudlines themselves. There is usually abundant tropical moisture up to 700 hPa, with drier air above. Dry-adiabatic or superadiabatic lapse rates are often present below about 900 hPa. The remaining levels are convectively unstable, and lifted indices are near or below zero. No attempt has been made to construct 'mean waterspout soundings'. The reasons become clear upon examination of [Figure 13](#), showing spiral-ascent aircraft temperatures beneath and just outside a cloudline that produced seven sequential waterspouts. The Key West sounding, taken earlier that day some 20 km from the cloudline, is also

plotted. Note especially the observed superadiabatic lapse rate up to about 300 m msl. The outflow from a nearby shower apparently contributed to the greater instability beneath this cloudline (air and sea temperatures obtained during another research flight also indicated a superadiabatic lapse rate in the subcloud layer on another day). If these results hold in general, they strongly suggest that the low-level thermodynamic properties of the waterspout environment are poorly represented by conventional land-based soundings.

Waterspout Risks and Hazards

Is a waterspout merely any tornado over a water surface (as defined in the American Meteorological Society's revised *Glossary of Meteorology*) or is there some fundamental difference in structure and energetics? More to the point, most waterspouts are, indeed, nonsupercell tornadoes over a water surface. The primary risk from waterspouts is to residents, mariners, and structures in coastal areas and large inland lakes. The first documented death from a waterspout in the US was a wind-surfer along the Lake Michigan waterfront in Chicago in July 1993. There are some well-documented cases of large vessels being capsized or de-masted by large waterspouts, and some other reports of boats being swamped with deluges of heavy rain and/or sea spray.

Even though tornadic waterspouts appear to be quite rare, impressive damage may occur. The author noted that two eyewitnesses to the landfall of the second, intense waterspout at Lower Matecumbe Key, FL, claimed that a 1965 Cadillac weighing over 2 t was 'lifted a few feet off the ground and then set down again'; and what surely was a tornadic waterspout slammed into Venice, Italy, in the late evening of 4 September 1970. The whirlwind killed at least 18 persons when it lifted a crowded passenger motorboat from the water and sent it to the bottom of a lagoon in less than a minute. The wind picked up the 25 t boat, lifted it into the air, turned it around several times, and then plunged it back into the water. Most recently, the author and collaborators studied a tornadic waterspout that originated over south St Petersburg, FL, on 12 July 1995, producing F1 damage (\$200 000) and injuring one person before moving offshore and growing over Tampa Bay.

That waterspouts pose a serious threat to structures lying along their paths at landfall is beyond doubt, based on studies by the author, Fujita, and Macky. For example, Fujita and colleagues found that about one-fourth of the typhoon-associated tornadoes affecting the Japanese islands over a 22 year period *originated as intense waterspouts*. Damage statistics indicate that tornadoes of waterspout origin in Japan are stronger on the average than those originating over land. Many of the damaging tornadoes affecting the central and eastern Gulf Coast during the late fall and early spring originate over the northern Gulf of Mexico as intense waterspouts. For example, an intense waterspout made landfall on 7 February 1971 at 1618 local time and caused \$3 million in damage in Pensacola, FL. More recently, a very destructive outbreak of tornadoes in the Tampa Bay area on 3 October 1992 began when an intense tornadic waterspout moved onshore in Pinellas County. The author has shown that about 10% of the waterspouts each summer in the Keys reach

Figure 19 Composite schematic model of a mature waterspout/spray vortex (stage 4) in the waterspout life cycle. For scaling reference, the maximum funnel diameters in this stage, just below the ‘collar cloud’, range from 3 to 140 m. See text for more details on structural, flow and thermal features. Compare with actual case photographs in [Figure 21\(f\)–\(i\)](#).

tornadic size and intensity, with peak velocities in the spray vortex of 50 m s^{-1} or more.

Another hazard from waterspouts is public misconception about their own personal risk. Unfortunately, we have seen some mariners in recent years actually chasing waterspouts! A spectacular and foolish case of such a waterspout chase is shown in the aerial photograph in [Figure 14](#), which shows a large outboard motorboat chasing a fully developed intense waterspout and towing a water-skier at the same time. This illustrates a sad example of putting oneself (and others) directly in harm’s way.

Waterspout Kinematics and Dynamics

The chance aerial encounter with the three waterspouts near Lower Matecumbe Key, FL, on 2 September 1967 provided a unique opportunity to learn more about their structure and wind fields. Photogrammetry with the use of transparencies taken by the author revealed that the largest waterspout funnel ([Figure 2](#)) varied in diameter from 38 m near the parent cloud

base to 21 m at its lower end. Using the dimensions of the surface spray vortex obtained with the slides and then tracking and timing the rotation of spray plumes and particles at various radii on the aircraft movies, we obtained a tangential velocity profile through the spray vortex.

The resulting three-dimensional model synthesized from data on the two major waterspouts is shown in [Figure 15](#), which includes an inset showing the measured tangential speed profile across the spray vortex of the most intense waterspout. The reader should compare [Figure 15](#) with the earlier models depicted in [Figures 4–6](#).

The derived tangential wind speed profile through the waterspout’s spray vortex closely approximates that of a *Rankine-combined vortex*. With the ordinate axis as tangential wind speed (V_t) in meters per second and the abscissa as radius (R) in meters, we note that the maximum tangential wind speed was 65.0 m s^{-1} or 130 kn at a radius of just 12 m from the vortex center. In atmospheric dynamics, it is often assumed that the cyclostrophic wind is a valid approximation to the real wind in tropical cyclones in equatorial latitudes and in small-scale

Figure 20 Composite model of decay (stage 5) in waterspout life cycle. Note that in some cases, the shower outflow line (labeled ‘density-surge line’) may be closely followed by the heavy rain shower. Also, the funnel cloud often undergoes rapid changes in shape and may become greatly contorted late in stage 5. For scaling purposes, maximum funnel diameters range from 3 to 105 m. Compare with actual case photographs in [Figure 21 \(j\), \(k\)](#).

vortices with very great wind speeds and path curvature. However, the data show that at times in a given waterspout’s life cycle, there may be horizontal accelerations of inflow into the spray vortex, especially from the right-rear quadrant relative to the direction of vortex motion. This feature would tend to obviate the possibility of a cyclostrophic balance in such cases.

The most intense waterspout documented by aircraft in 1969 was anticyclonic, and photogrammetric analysis of movies yielded peak tangential wind speeds in the spray vortex of 88 m s^{-1} at $R = 9 \text{ m}$. We also found that about 10% of the waterspouts each year in the Keys are *anticyclonic*, and a few of these may also be tornadic (peak rotational velocities in the spray vortex in excess of 50 m s^{-1}).

The Waterspout Life Cycle and Interacting Scales of Motion

The 1969 Lower Keys Waterspout Project and subsequent field programs over the intervening years reveal that all waterspouts undergo a regular life cycle composed of five discrete but overlapping stages: (1) the *dark spot stage*, characterized by a prominent light-colored disc on the sea surface, surrounded by a dark patch diffuse on its outer edges – the dark spot may or may not have a small funnel cloud above it initially, but signifies a complete vortex column extending from cloud base to sea surface; (2) the *spiral pattern stage*, the primary growth phase of the waterspout, characterized by the development of

Table 2 1969–70 statistical summary of documented stages in waterspout life cycle

Stage Major feature	1 Dark spot	2 Spiral	3 Spray ring	4 Spray vortex	5 Decay
1969: of 95	66 initially observed in stage 1	16 had spirals, and smoke flares showed circulation on this scale in several other cases	56 attained the sustained stage 3; short duration, transitional stage	51 reached this stage	51 decayed as heavy showers or cool outflow overtook spout; also 33 dark spots simply decayed by fading away
1970: of 33	All initially observed in stage 1, and 17 had an associated funnel at some time in the life cycle. $V_{\text{max}} = 10\text{--}15 \text{ m s}^{-1}$ in broad band just outside circular light-colored disc	Only 7 evolved to this stage and beyond; $d_s \sim 150\text{--}1000 \text{ m}$	$V_{\text{max}} \geq 22 \text{ m s}^{-1}$ in narrow band around dark spot periphery	86 had an associated funnel at some time in the life cycle; $V_{\text{max}} \geq 85 \text{ m s}^{-1}$ in sharply defined peak just outside ‘eye’ of spray vortex in bright band of concentrated spray	Some spiral rain curtains observed around decaying waterspouts
Duration range of stage (1969–70)	$t_1 = 1\text{--}22 \text{ min}$	$t_2 = 2\text{--}7 \text{ min}$	$t_3 = 1\text{--}2 \text{ min}$	$t_4 = 2\text{--}17 \text{ min}$	$t_5 = 1\text{--}3$; up to 7 min

Figure 21 Sequence of photographs, by the author, of the complete life-cycle of a large, cyclonic waterspout in cumulus cloudline 20 km north of Key West, FL, in the late morning of 10 September 1969. This was the largest of nearly 100 waterspouts documented by research aircraft during the summer 1969 Lower Keys Waterspout Project. (a). Approach to building east–west oriented cumulus congestus cloudline (cloud base measured at 600 m). (b) Dark spot stage. Note the large dark spot, with a bright inner disc surrounded by a darker patch on the sea surface, and a large truncated funnel above. View from aircraft orbiting near cloud base, looking southwest with Keys in the background. Compare with Figure 16. (c) Dark spot stage – telephoto of dark spot. Note the small wind-driven waves approaching and apparently encroaching the dark spot from the left center. Water depths were 12–15 m, and only a horizontal cyclonic shear of about $\pm 15 \text{ m s}^{-1}$ could be detected across the 90 m diameter of this dark spot. Compare with Figure 16. (d) Late spiral-pattern stage, with incipient spray ring and elongation of dark ‘shear band’ around the eastern semicircle of the vortex, looking south at 1054 EST, 10 September 1969. Compare with Figure 17. (e) Preexistent shear band (far left) and newly developed spiral pattern at 1057 EST, looking west. Spray ring now fully developed and intensifying. Compare with Figure 18. (f) View of mature stage showing spray vortex, rope-like funnel and complete spiral pattern on sea surface. Looking NE at 1059 EST. (g) Looking SE at 1100 EST, with outer funnel wall developed downward from cloud base, and intense spray vortex on sea surface. (h) Large, double-walled waterspout funnel and spray vortex with trailing wake at 1103 EST. Compare with Figure 19. (i) Lower portion of the large waterspout, now with single-walled funnel, and spray sheath rising helically upward around spray vortex, with eye; looking ESE at 1105 EST. (j) Onset of decay stage, with protuberances moving around funnel walls and weakening spray vortex below; view towards south-west at 1107 EST. (k) Decay stage, with funnel narrowing and retracting, spiral pattern gone and spray vortex expanding with large eye. Note the smoke flare on the sea surface on the right and heavy showers in the background (waterspout moving away from showers, with cooler outflow intercepting waterspout). Compare with Figure 20.

Figure 21 (continued).

alternating dark- and light-colored bands spiraling around the dark spot on the sea surface; (3) the *spray ring (incipient spray vortex) stage*, characterized by a concentrated spray ring around the dark spot, with a lengthening funnel cloud above; (4) the *mature waterspout stage*, characterized by a spray vortex of maximum intensity and organization, the gradual weakening of the spiral pattern, and maximum funnel cloud length

and diameter; and (5) the *decay stage*, when the waterspout dissipates (often abruptly) as it is intercepted by the cool downdrafts from a nearby rain shower. The five stages of the waterspout life cycle are depicted conceptually in [Figures 16–20](#), respectively.

Not every waterspout observed from its inception evolved through all other stages; however, the combinations of stages

Figure 21 (continued).

1–2–3–4–5, 1–2–5, 1–3–4–5, and 1–5 have been documented. All waterspout cases documented by aircraft-based field programs during 1969–70 are summarized in [Table 2](#). Stages 1 and 4 have the greatest range of duration and often comprise the bulk of a waterspout's total lifetime. The largest and best-documented waterspout observed from aircraft during the 1969 Lower Keys Waterspout Project is shown in [Figure 21\(a\)–\(k\)](#). This sequence illustrates the evolution and key structural features of a complete waterspout life cycle.

Waterspouts' Relation to Other Convective Vortices

Other research and field projects by Peter Sinclair have shown many flow similarities between waterspouts and dust devils. The major difference seems to be one of scale and the fact that dust devils are associated with dry convection (no parent cloud system) in very hot climates. The high formation frequency and the life cycle of waterspouts in the Florida Keys result from energy and angular momentum exchanges among five scales of atmospheric circulation. These are: (a) the *funnel scale*, corresponding to the waterspout itself, with funnel diameters ranging from 3 to 150 m; (b) the new *spiral scale*, ranging from 150 m to 1 km on the sea surface; (3) the *individual cumulus-cloud scale*, ranging from less than 1 to up to 5 km in diameter; (d) the *cumulus-cloudline scale*, ranging from 5 to 100 km in

length; and (e) the *synoptic scale*, extending several hundreds of kilometers horizontally. The order of presentation of interacting scales does not imply the sense of energy or momentum transfer. In fact, a more detailed discussion of this scale-interaction process by the author suggests that the funnel scale is the end product of vorticity concentrated by larger-scale convergence fields.

The tornado life cycle resembles, in many respects, that typical of Florida Keys waterspouts. Both commence with surface evidence of vortex existence before a funnel cloud has descended a significant distance toward the surface. Approaching the mature stage, the tornado and waterspout exhibit spiral inflow characteristics with a distinct boundary between warm, moist air and cool, dry air. A schematic plan view of composited mean subcloud-layer mesoscale flow around the Union City tornado during its mature stage is given in [Figure 22](#). The cooler air mass from a nearby precipitation area apparently cuts off flow of warm, moist air into the tornado's circulation, leading to vortex decay. The visible funnel becomes thin, increasingly tilted and contorted as it dissipates. Major differences between the tornado and waterspout appear to be vortex and parent cloud scales and, to a lesser extent, vortex lifetimes and intensities. Both vortices may evolve rapidly through their respective life cycles without evolving through every stage. We note the strong resemblance, apart from scale, between the preexistent dark 'shear band' from which the

Figure 22 Composite schematic of mean subcloud flow around Union City, OK, tornado during its mature stage (1550–1555 CST), 24 May 1973. The position of the NSSL intercept team is plotted relative to the tornado ('T'), rain, and hail at Union City. RW: showers; TRW: thundershowers. Main parent storm cloud boundaries are scalloped.

Figure 23 For the waterspout shown in **Figure 21(a)–(k)**, composite streamline (solid) and isotach (dashed in m s^{-1}) analysis of boundary layer flow on spiral scale around a mature waterspout on 10 September 1969, derived from the analysis of smoke plumes and photogrammetry of spiral features. During the period of compositing of marine flare data, we have assumed that the boundary layer circulation of the waterspout is a permanent-type system, i.e., quasi-steady state, as the spray vortex advances toward the smoke flares. At each instant of time, therefore, a streakline approximates a relative streamline.

waterspout's spiral pattern evolved (Figure 23, see also Figure 21 (d),(e),(f)) and the flanking cumulus cloudline in Figure 22 which spirals into the rotating 'wall cloud'. Both the flanking line and waterspout shear band appear to be the demarcation of gust fronts from nearby precipitation, and both signify pronounced low-level wind discontinuities with large cyclonic shear (vorticity). A recent study was made by the author and National Weather Service collaborators of a large waterspout that originated over land as a destructive tornado in St Petersburg, FL, and then tracked south-eastward over Tampa Bay with a 30 min lifetime. It was found that the tornadic waterspout's parent storm developed rapidly in response to surface mesoscale boundary interactions.

Introduction

Windstorms produced by complexes of convective storms (thunderstorms) pose a significant hazard to life and property in many places of the world, especially during the spring and summer months. The largest and most long-lived of these events have been given a generic name of 'derecho,' a term that originated in the late 1800s to refer to convective systems producing wide and long swaths of straight-line wind damage. Detailed studies of convective wind events, however, have shown that a vast majority are associated with a particular type of organized convective system, more popularly referred to as a 'bow echo.' This article describes the basic structures and environments associated with bow echoes and derechos, and further highlights some of the recent research that clarifies the mechanisms critical to their development and maintenance.

Bow echoes and derechos form a subset under the more general heading of mesoscale convective systems, which include squall lines, mesoscale convective complexes, and the like. In all of these cases, the system is envisioned to be composed of a sequence of relatively independent convective cells that contribute collectively to a larger system-scale structure. The individual convective cells can be ordinary cells, multicells, or supercells, as described elsewhere in the encyclopedia (see *Mesoscale Meteorology: Convective Storms: Overview*). In the following, the system-scale attributes that have led to these particular systems being identified for their unique form of mesoconvective organization are emphasized.

Bow Echoes

Bow echoes, originally referred to as a line echo wave pattern (LEWP), are most readily identified by a persistent bow shape

on a radar screen, and have become especially associated with the production of long, narrow swaths of damaging surface winds. Much of what is known observationally concerning bow echoes originated with Dr TT Fujita, who spent much of his career trying to characterize and understand the types of convective systems most apt to produce severe weather such as downbursts and microbursts.

A typical evolution and morphology of radar echoes associated with a severe bow echo is presented in [Figure 1](#). The system usually begins as a strong convective cell or a short line of convective cells that may be either isolated or embedded within a more extensive squall line. As the strong surface winds develop, the initial cell evolves into a bow-shaped line segment of cells, with the strongest winds occurring near the apex of the bow. Cyclonic and anticyclonic motions of the radar cells are often noted on the northern and southern ends of the bow segment, respectively. During the declining stage, the system often evolves into a comma-shaped echo with predominantly cyclonic motion of the radar echoes evident on the northern end of the system ([Figure 1\(e\)](#)).

At the core of most bow echoes is a strong surface cold pool and associated surface mesohigh, which is produced via the evaporation of rain and transport of potentially colder air to the surface from the mid-troposphere (e.g., 3–5 km above ground level (AGL)). Cold pools within severe bow echoes can be as much as 10–15 °C colder than the surrounding air mass, with surface pressure excesses reaching 5–8 mbar. In association with this cold pool is also often an intense rear-inflow jet that extends rearwards from the leading edge of the active convection and may extend in depth from 3 to 5 km AGL down to the surface. This rear-inflow jet helps transport drier, mid-level air into the precipitating region behind the leading edge of the convection, increasing the potential for strong,

Figure 1 A typical morphology of radar echoes associated with bow echoes that produce strong and extensive downbursts, labeled DB on the figure. Reproduced from Fujita, T.T., 1978. Manual of downburst identification for project Nimrod. Satellite and Mesometeorology Research Paper No. 156. Department of Geophysical Sciences, University of Chicago.

evaporationally produced downdrafts and resulting cold pools. Such rear-inflow jets can reach magnitudes of 25 m s^{-1} or greater above the ambient mid-level flow. The cold pool and rear-inflow jet represent the primary source for the strong surface winds in such systems.

Bow echoes are observed over a wide range of scales, from tens of kilometers to over 200 km (along line length) in extreme cases. Lifetimes can range from a couple of hours to over 10 h. Although a range of scales is observed, the most intense bow echoes tend to be 40–120 km in length and have lifetimes of 4–6 h. Widespread surface winds of 25 m s^{-1} or greater are commonly observed with severe bow echoes, with extreme cases producing swaths of damaging winds of greater than 50 m s^{-1} , producing widespread falls of trees, toppling power poles, damaging buildings, and blowing vehicles off highways.

An example of bow echo that passed through Springfield, Illinois, on 6 August 1977 is presented in Figure 2. This system evolved from a relatively isolated cell to a comma-shaped echo over a 5 h period while producing a continuous swath of damaging surface winds over a 200 km path. A detailed damage survey taken during a portion of this event is presented in Figure 3, and demonstrates that the broad swath of outflow winds is often made up of a series of individual downdrafts and microbursts (see *Mesoscale Meteorology*: Microbursts). It also demonstrates the tendency of bow echoes to generate tornadoes, especially along and to the north of the apex of the bow (Figure 2). In the present case, 18 tornadoes were generated just to the north of the bow echo apex as the northernmost cell evolved into a cyclonically rotating head. The relationship between bow echoes and tornadoes has still not been adequately explained.

A wide range of radar echo configurations can be associated with developing severe bow echoes (Figure 4). One of the

common characteristics is the development of a strong low-level reflectivity gradient near the leading edge of the concave-shaped echo. Another significant feature is the presence of a weak echo channel or 'rear inflow notch' (RIN) on the backside of the bow, which often signifies the location of the intense rear-inflow jet and the likelihood of downdraft winds and possible downdraft-induced tornadoes. Also, while a bow echo is generally organized on a scale larger than a single convective cell, individual severe cells, sometimes supercellular, may be contained within the larger scale structure (e.g., note the 'intense convective cell' with the tight reflectivity gradient and hooklike appendage at the southern end of the bow echo in Figure 4).

Another example of a mature bow echo is shown in Figure 5 from 5 May 1996 near Paducah, Kentucky. In this example, a large bow-shaped convective system has two smaller scale bows embedded with the larger circulation. The Doppler winds clearly depict a large rear-inflow jet behind the core of the system (dark blue), with weak anticyclonic shear to the south of the bow and stronger cyclonic shear evident on the northern end of the bow. Additionally, the smaller embedded bows each have their own localized rear-inflow jets with associated rotational features on the ends. This event emphasizes that a range of bow-echo scales can exist, sometimes side by side, in the same basic environment. A vertical cross section of reflectivity taken through the core of the bow (Figure 6(a)) depicts strong, upright convective cells at the leading edge, with a weaker stratiform region extending rearward. A storm relative velocity cross section (Figure 6(b)) depicts front-to-rear ascending flow through the convective cells and extending aloft within the anvil, with a strong rear-inflow jet beneath the front-to-rear flow at mid-levels.

Satellite and Mesometeorology Research Paper No. 156. Department of Geophysical Sciences, University of Chicago.

Figure 3 Eighteen tornadoes, 10 downbursts, and 17 microbursts are depicted in this map. One tornado (No. 11) was anticyclonic. Apparently, eight tornadoes formed on the left side of microbursts. No trace of downbursts was found in the vicinity of other tornadoes. Reproduced from Fujita, T.T., 1978. Manual of downburst identification for project Nimrod. Satellite and Mesometeorology Research Paper No. 156. Department of Geophysical Sciences, University of Chicago.

Derechoes

The term 'derecho' is used to describe convective systems that produce straight-line convective wind gusts greater than 26 m s^{-1} within a concentrated area with a major axis length of at least 400 km. The gusts must also show a systematic pattern of progression, with no more than 3 h elapsing between successive wind damage events. Such systems have been observed to have lifetimes of as long as 18 h, producing a swath of damaging winds hundreds of kilometers wide and 1000 km long. An example of the extent and longevity of a derecho event is presented in Figure 7. In this case a squall line produced damaging wind over a swath hundreds of kilometers wide and 1000 km long over 18 h.

Two basic patterns of radar cells are often associated with a derecho (Figure 8). The first pattern (referred to as a progressive derecho) consists of a single bowed segment of convective cells that often develop just on the cool side of a weak stationary front. The bowed feature moves parallel to the front. The second pattern (referred to as a serial derecho) consists of a longer squall line that has evolved into a series of bow echoes or LEWPs that propagate along the squall line.

While bow echoes represent one of the primary convective structures associated with derecho events, severe bow echoes occur much more frequently than derechos, producing damaging surface winds over more limited regions and for shorter time periods than included in the strict definition of a derecho.

Bow Echo and Derecho Environments and Climatology

Bow echo and derecho environments are generally characterized by large amounts of convective instability and low-level moisture. Surface dew points are commonly greater than 20°C with lifted indices averaging about -9°C . Convective available potential energy (CAPE) is generally greater than 2000 J kg^{-1} , with many cases exhibiting CAPEs greater than 4000 J kg^{-1} . Such large CAPEs support both the development of strong convective updrafts as well as strong convective downdrafts and cold pools, the latter being especially critical for the development of strong surface outflow. The development of strong cold pools can also be supported by dry mid-tropospheric conditions, although bow echoes and derechos are observed for both moist and dry mid-level conditions as long as sufficient

Velocities are presented relative to a storm motion of 20 knots (10 m s^{-1}) from 277° . For (b), green colors represent flow toward the radar, while red colors represent flow away from the radar. Przybylinski, R.W., personal communication.

CAPE is available. Environmental vertical wind shear magnitudes tend to be in the moderate range for severe convective events, with about 15 m s^{-1} of shear evident between the surface and 700 mbar (roughly 0–3 km AGL), and about 20 m s^{-1} between the surface and 500 mbar (roughly 0–6 km AGL). Such shear magnitudes are generally weaker than are associated with supercell storms, although bow echoes and derechos are observed in these more strongly sheared environments as well.

Bow echoes and derechos can occur in environments with strong synoptic-scale forcing, as with severe, prefrontal squall

lines, but also occur quite often in association with more benign synoptic patterns. As presented in Figure 9, many events begin along or to the north of a weak east-to-west oriented quasistationary frontal boundary, in the vicinity of a mid-tropospheric ridge, and then move along the boundary (as in the progressive bow echo in Figure 8). The existence of a low-level jet (LJ) impinging from the south and flowing along the frontal region, along with the polar jet (PJ) oriented parallel to the front farther to the north, leads to moderate magnitudes of vertical wind shear in the lower and mid-troposphere. The addition of enhanced low-level convergence along the zone, to

Figure 7 Area affected by the convective windstorm of 5 July 1980 (dashed line). Three-hourly squall line positions are indicated in UTC (from 03.00 to 21.00 on 5 July). Officially measured convective gusts are indicated by wind barbs (full barb signifies 5 m s^{-1} , flag signifies 25 m s^{-1}). Personal injuries (67) are indicated by dots, and each death (6) is shown by an 'x'. Reproduced from Johns, R.H., Hirt, W.D., 1987. Derechos: Widespread convectively induced windstorms. *Weather and Forecasting* 2, 32–49.

help initiate the convection, along with the associated deepening of the moist layer, to help increase the thermodynamic instability, fills out the ingredient list that promotes the development of bow echoes and derechos for this type of weather pattern.

Figure 10 shows the paths of 67 well-defined derecho events over the USA during the period of 1983–93. A primary corridor of derecho activity is evident over the upper mid-western states, with secondary corridors along an axis from Kansas through Oklahoma and Texas, and also in the southeast. As presented in Figure 11, derechos are most frequent during the spring and summer months over the USA, but can occur at almost any time of the year. A similar climatology is believed to exist for the even more frequent smaller scale, shorter lived bow echoes, although a specific study documenting bow echo occurrence has yet to be undertaken.

Numerical and Dynamical Studies

The tendency for a convective cell to evolve into a bow-shaped system of cells for certain environments is readily reproduced in numerical cloud modeling studies. Fundamentally, an updraft produces rain that falls and evaporates, thereby producing a pool of cold air that spreads along the ground. This spreading cold pool produces convergence and lifting along its leading edge that can then trigger new cells. However, rather than a cold pool producing a complete circle of new cells around the initial storm, cells are favored along a bow-shaped arc oriented perpendicular to the vertical wind shear vector. The ability to trigger new cells along this arc increases dramatically as the amount of vertical wind shear increases, and also if the wind shear is confined to the lowest 2–5 km AGL.

Figure 12 demonstrates these results for numerical model simulations of bow echoes, with and without the effects of the Earth's rotation (Coriolis forcing) included. These simulations are initiated with five convective cells along a line 150 km in length in a horizontally homogeneous environment with moderate CAPE (2200 J kg^{-1}) and strong low-level vertical wind shear (20 m s^{-1} over the lowest 2.5 km AGL; winds are kept constant above 2.5 km). In both cases, a line of strong convective cells has become established by 3 h. For the non-Coriolis case (Figure 12(a)), this line becomes significantly bow-shaped between 3 and 6 h, with strong mirror image cyclonic and anticyclonic vortices developing at mid-levels behind the northern and southern ends of the system, respectively. With Coriolis forcing added (Figure 12(b)), the northern cyclonic line-end vortex strengthens over time, while the southern anticyclonic vortex weakens, leading to a highly asymmetric system configuration by 6 h. The strengthening of the northern cyclonic vortex is directly related to the mid-level convergence of planetary rotation. Figure 12(b) also demonstrates that a range of bow-echo scales can be produced within the same convective system, very similar to the observations of the Paducah bow echo case from 5 May 1996 (Figure 5). The tendency to develop such subsystem-scale vortices within such simulations increases with increasing magnitudes and depth of the ambient vertical wind shear.

Much of the strength and structural characteristics of bow echo-type systems can be understood by considering the development of a two-dimensional circulation along a vertical cross section through the core of the convective line. This is most easily accomplished via the two-dimensional horizontal vorticity equation for inviscid, Boussinesq flow (eqn [1]), where $\eta = \partial u / \partial z - \partial w / \partial x$ and B represents the buoyancy, defined by eqn [2].

Figure 8 Schematic representation of features associated with (a) progressive and (b) serial derechos near the midpoint of their lifetimes. The total area affected by these derechos is indicated by the hatching. The frontal and squall line symbols are conventional. Reproduced from Johns, R.H., Hirt, W.D., 1987. Derechos: Widespread convectively induced windstorms. *Weather and Forecasting* 2, 32–49.

$$\frac{d\eta}{dt} = -\frac{\partial B}{\partial x} \quad [1]$$

$$B \equiv g \left[\frac{\theta'}{\bar{\theta}} + 0.61(q_v - \bar{q}_v) - q_c - q_r \right] \quad [2]$$

Here θ represents the potential temperature, q_v , q_c , and q_r represent the mixing ratio of water vapor, cloud water, and rainwater, respectively, and g is the acceleration due to gravity. Within this framework, the only source of horizontal vorticity other than the ambient vertical wind shear (e.g.,

$\eta = \partial U(z)/\partial z$, where $U(z)$ represents the ambient wind profile) is horizontal gradient of buoyancy. Thus, the analysis of the development of circulation is simplified for understanding the evolution of the buoyancy field and its interaction with the ambient shear. The two primary sources of buoyancy within a convective system are the warm convective updraft and the cold convective downdraft and cold pool. The net circulation of the system thus depends on the relative strengths of the ambient shear, the convective updrafts, and the cold pool.

From the perspective of eqn [1], a convective system initially leans in the direction of the ambient vertical wind shear vector (e.g., downshear) as the warm convective updraft feels the influence of the sheared flow (Figure 13(a)). However, as the surface cold pool develops and strengthens over time, the opposing circulation associated with the cold pool forces the system to achieve a more upright (Figure 13(b)) and then upshear-tilted (Figure 13(c)) configuration. Once the system begins to tilt upshear, a rear-inflow jet is generated in response to the buoyant front-to-rear ascending current aloft and rearward spreading cold pool at the surface. For most convective systems, this rear-inflow jet descends and spreads along the surface well behind the leading edge of the convection, enhancing the surface outflow but generally weakening the convective system. For the stronger shear, large CAPE bow echoes, however, this rear-inflow jet may remain elevated, enhancing the lifting at the leading edge of the system, and promoting an even stronger, and more long-lived convective system (Figure 13(d)). This configuration of the vertical circulation and elevated rear-inflow jet is quite similar to the 5 May 1996 case, as presented in Figure 6.

Figure 9 Idealized sketch of a mid-latitude warm season synoptic-scale situation especially favorable for development of long-lived progressive bow echo complexes producing extensive swaths of damaging winds. The line B–M–E represents the track of the bow echo complex. Thin lines denote sea level isobars in the vicinity of a quasistationary frontal boundary. Broad arrows represent LJ stream and PJ in the upper troposphere. Reproduced from Johns, R.H., Doswell III, C.A., 1992. Severe local storm forecasting. *Weather and Forecasting* 7, 588–612.

Figure 11 Monthly distribution of derecho events over the central and eastern USA for the years 1983–93, for the events shown in Figure 10. Events are also subclassified based on the relative strength of the synoptic-scale forcing, as either strong forcing (SF), weak forcing (WF), or hybrid events. Adapted from Evans, J.S., Doswell III, C.A., 2000. Examination of derecho environments using proximity soundings. *Weather and Forecasting* 16, 329–342.

Figure 12 Horizontal cross sections of system-relative flow, rainwater mixing ratio, and vertical velocity at 2 km AGL for the $U_s = 20 \text{ m s}^{-1}$ 2.5 km shear (a) non-Coriolis and (b) Coriolis simulations at 3, 4.5, and 6 h, respectively. Vectors are presented every four grid points (8 km), with a vector length of 8 km equal to a wind magnitude of 20 m s^{-1} . The rainwater is contoured for magnitudes greater than 1 g kg^{-1} (lightly shaded) and magnitudes greater than 3 g kg^{-1} (darkly shaded). The vertical velocity is contoured at 5 m s^{-1} intervals, with the zero contours omitted. A domain speed of $u_m = 18.5 \text{ m s}^{-1}$ has been subtracted from the flowfield. Tick marks are spaced 20 km apart. Adapted from Weisman, M.L., Davis, C., 1998. Mechanisms for the generation of mesoscale vortices within quasi-linear convective systems. *Journal of the Atmospheric Sciences* 55, 2603–2622.

System strength and severity are enhanced even further through the development of the line-end vortex pair (e.g., Figure 12(a)), which focuses and strengthens the mid-level rear-inflow jet, thereby enhancing the resultant convective downdrafts and surface outflow. The source of this line-end vorticity is both the downward tilting of the ambient vertical wind shear layer as well as upward tilting of the system-generated vertical wind shear associated with the ascending updraft current and descending rear-inflow jet.

The processes described above contribute to the evolution of all convective systems, but produce severe weather

for a relatively restricted range of environmental conditions. Generally, long-lived, severe wind-producing convective systems, such as bow echoes and derechos, are produced in idealized simulations for environments with at least 2000 J kg^{-1} of CAPE and at least 10 m s^{-1} of vertical wind shear over the lowest 2–5 km AGL. However, the more coherent systems with significant bookend vortices and strong, elevated rear-inflow jets, as presented in Figure 12, are restricted to environments with at least $15\text{--}20 \text{ m s}^{-1}$ of vertical wind shear over the lowest 2–5 km AGL.

Figure 13 Four stages in the evolution of an idealized bow echo developing in a strongly sheared, large CAPE environment. The updraft current is denoted by the thick, double-lined flow vector, with the rear-inflow current is (c) denoted by the thick solid vector. The shading denotes the surface cold pool. The thin, circular arrows depict the most significant sources of horizontal vorticity, which are either associated with the ambient shear or which are generated within the convective system, as described in the text. Regions of lighter or heavier rainfall are indicated by the more sparsely or densely packed vertical lines, respectively. The scalloped line denotes the outline of the cloud. Density Currents

PG Baines, University of Melbourne, Melbourne, VIC, Australia

Synopsis

Density currents (also known as ‘gravity currents’) in the atmosphere are air flows that are principally due to differences in density (i.e., temperature) between the neighboring bodies of air. Descending cold dense bodies of air are sometimes termed ‘katabatic flows’ or ‘katabatic winds’ at the ground level and ascending heated air constitutes the ‘anabatic winds.’ Such density differences cause lateral pressure gradients, which produce horizontal motion, with cold air moving over the ground into a warmer air mass. They occur on length scales ranging from several hundred meters to hundreds of kilometers. The Earth’s rotation (via the Coriolis force) is normally not important for these flows, unless they extend over distances of 100 km or more. In this article, some examples of these flows are provided, and their basic dynamical properties for flows over horizontal ground that move in one direction and that which move radially outward in two dimensions are described, and then density currents that flow downslopes, taking into account the effects of radiative forcing and environmental stratification, are discussed.

Examples

Atmospheric examples of such flows are common. They include *sea breezes*, in which heating of the air over the land by convection from the solar-heated surface below causes a lateral density difference between that and the relatively cooler air over the ocean. The onshore-flowing sea breeze is the result. Similarly, the weaker offshore nocturnal *land breeze* occurs due to radiative nocturnal cooling over the land. Radiative cooling of the air causes flow down sloping topography, forming *drainage flows*, and *valley winds*, particularly at night. Another source is thunderstorms, which contain downdrafts of cold air due to the drag of falling raindrops, and cooling because of their evaporation. On reaching the ground, these downdrafts spread and form density currents. Cold fronts usually contain one or more squall lines, which consist (by definition) of a line of thunderstorms, so that the associated downdraft-produced density currents are conspicuous features of cold fronts. Such flows are sometimes made visible by suspended dust, which mark out the features of the cold density current. Noted examples of these are seen in the Sudan (where they are known as *haboobs*), and in India, Australia, and Arizona during dry summers. In these flows the dust usually makes a negligible contribution to the density difference, but this is not the case in another example of density currents – *powder snow avalanches*. Here turbulence causes the snow to be suspended in the air, producing the density difference that causes the downflow, which in turn produces the turbulence.

Unidirectional Density Currents

The dynamical essentials of the above phenomena can be encapsulated by looking at simple idealized flows that represent them. These can best be seen from simple laboratory experiments. Here water is used to represent air, because both are effectively incompressible for motions on these length and time scales. A density current can be created in the laboratory by releasing cold water into relatively warmer water, but it is

usually simpler to work with isothermal fresh water and use dissolved salt to make the water denser. In **Figure 1** a body of dense salty water has been released into a tank of fresh water, producing a density current moving from left to right over a horizontal surface, viewed from the side. The leading part of the current consists of a ‘head’ with an overhanging leading nose. This head may be regarded as a limiting form of hydraulic jump in a cold layer of dense fluid, in which the depth of this layer upstream of the jump is zero. Behind the head the fluid has a three-layer structure. The layer of dense fluid constituting the main part of the current is at the bottom. This fluid moves faster than the head, and catches up with it. There it rises and is mixed with the surrounding lighter environmental fluid, and forms a density-stratified layer, spread out above the bottom current. Vorticity is produced in the upper part of the head by shear between the head and the ambient fluid, and this is also deposited in the stratified layer. This mixed stratified layer moves slowly in the direction of the current. It is highly turbulent immediately behind the head, where most of the mixing takes place, and this turbulence decays with distance from the head. Here the interfaces between the mixed layer and

Figure 1 Shadowgraph showing the structure of the flow in and behind a density current head.

the dense fluid below and the environmental fluid above are generally stable, so that apart from the decaying turbulence little further significant mixing occurs.

Figure 1 shows a unidirectional gravity current head, averaged across its width by the shadowgraph technique. In fact, density current heads have three-dimensional structure, as shown in **Figure 2**. The leading edge contains many lumps and bumps, and these shapes change continually as the head propagates. Some small parts of the head are more advanced than others, but these then disappear and are overtaken by others. This *lobe* and *cleft* structure is due to the drag on the current by the rigid lower surface over which it propagates. This retards the lowest levels of dense fluid, causing the overhanging noses. The lighter fluid beneath these noses then rises through the dense fluid driven by its buoyancy difference, and this causes the unstable three-dimensional lobe and cleft structure that is seen in **Figure 2**. This structure can sometimes be seen in the atmospheric examples cited above, where dust or moisture make the cold air visible.

We may consider an idealized two-dimensional model of a density current, in which the volume flux Q and density ρ_1 of the dense fluid are specified at a given source location. If the density of the environmental fluid is ρ_0 , the buoyancy of the dense fluid is then $g' = (\rho_1 - \rho_0)g/\rho_0$. Behind the head, the velocity v_1 and thickness d_1 of the dense layer are approximately constant. We then have $Q = v_1 d_1$, and from dimensional analysis alone we have

$$d_1 \sim (Q^2/g')^{1/3}, \quad v_1 \sim (Qg')^{1/3} = (g'd_1)^{1/2} \quad [1]$$

The speed v_H of the head also scales with v_1 , with $v_H < v_1$. Laboratory observations of flow into a deep homogeneous environment at large Reynolds numbers give

$$v_H = 1.2(g'd_1)^{1/2}, \quad v_1 = 1.4(g'd_1)^{1/2} \quad [2]$$

which are approximately constant with time for a sustained source of fluid. The same observations also show that the total height of the head is typically $3d_1$, and the height of the nose is

Figure 2 A laboratory simulation of a density current, in which the dense fluid has been made visible by milk. Note the lobe and cleft structure of the dense fluid interface, and the low-level transient overhanging noses.

about $0.15d_1$. These expressions apply to density current heads in general, when the buoyancy and thickness of the dense fluid approaching the head are given by g' and d_1 . This steady pattern is maintained because the driving pressure gradient is dynamically balanced by loss of momentum through mixing in the head (see below), and the following current is restrained by friction with the bottom surface and the fluid above. When the current length becomes large the thickness of the dense layer decreases gradually away from the source, providing a small pressure gradient to overcome friction.

Unidirectional Density Currents due to Collapse of a Dense Body of Fluid

Density currents may also be created by suddenly releasing a large body of dense fluid within a stationary environment of lighter fluid. This models a finite-sized source, and is readily simulated in a laboratory tank by raising a vertical barrier that separates the dense and lighter fluid. In a two-dimensional situation where the fluid spreads in the x -direction only, the flow passes successively through three stages. In the first stage of collapse of the dense fluid (of initial depth d_0 , length L_0 , and area $A = A_0 = d_0 L_0$ in a fluid of total depth D_0), termed the *slumping* stage, the front travels as a density current of constant speed and depth. However, the surface of the dense fluid behind this front is not horizontal as large amplitude internal waves propagate on it (**Figure 3**). These waves reflect from the far end (or center, for a symmetric collapsing body), and the character of the flow changes when they catch up to the front, or density current head.

Density current propagation in the atmosphere is often significantly affected by upper level stratification. For example, it is common for sea breeze fronts to propagate inland under an atmospheric inversion, which acts as an effective lid. This may be represented in experiments by a finite total depth. If this is present, the resulting motion of the ambient fluid may affect the waves on the interface with the dense fluid, and hence affect the details of the slumping behavior. In particular, the presence of a reversed flow in the upper layer causes a corresponding reduction in the speed over the ground of the collapsing front, relative to eqn [2]. The distance x_s at which the slumping stage ends and the waves reach the head, measured from the end of the tank, is then observed to be

$$x_s/L_0 = 3 + 7.4d_0/D_0 \quad [3]$$

Figure 3 Schematic diagrams showing various stages at successive times in the initial slumping stage of the collapse of a rectangular volume (shown dashed) of dense fluid with $d_0/D < 1$.

After the reflected waves have caught up with the density current head the flow enters the second self-similar (inertio-gravity) stage, which is dominated by inertia, buoyancy, and mixing. Here the dense fluid collapses in the form of a rectangle of approximately uniform area, with increasing length and uniform decreasing height d_1 . This rectangular uniformity is maintained by internal waves propagating outward on the dense fluid interface. Mixing in the main body of the collapsing rectangular current is generally very small. This is because the mean gradient Richardson number at its upper boundary (on which mixing depends) is generally greater than 0.25, implying that the mean flow is stable and does not generate local mixing. Hence the density within the collapsing rectangular body of dense fluid remains largely unaltered until the fluid enters the head, where most of the mixing takes place. The total rectangular area $A(t)$ of unmixed dense fluid continually decreases because $v_1 > v_H$ in eqn [2]. During this stage, the length of the dense fluid increases as $(Ag't^2)^{1/3}$, so that the velocity of the density current head decreases with time as $(Ag'/t)^{1/3}$ because of the steady decrease of d_1 . This continues until the third stage is reached, where the motion becomes sufficiently thin and slow for viscous effects to become important, a regime that is not relevant here.

In the second stage, dense fluid enters the head from behind where it is mixed with environmental fluid. The result is spread out behind, in a layer over the dense layer. The rate of mixing within the head is roughly proportional to its mean height, and hence decreases with it. At early times in this stage ($x > x_s$), the detained mixed fluid consists mostly of the dense fluid with a small part of environmental fluid. However, as the current proceeds, this proportion reverses and near the end ($x \gg x_s$), nearly all the mixed fluid is environmental. When the end of the second stage has been reached (at $x = x_s + 29A_0^{1/2}$), and mixing has effectively ceased, the total volume of mixed fluid that has been produced is slightly more than twice the initial volume of dense fluid. The volume of the remaining unmixed dense fluid is quite small, so that overall, the dense and environmental fluids have been mixed in approximately equal proportions.

Radial Density Currents

In the atmosphere, collapsing localized bodies of dense fluid may be constrained to spread in one direction if they are spatially confined such as in a valley. However, this is usually not the case for thunderstorm downdrafts, for example, which are often free to spread horizontally without confinement. These and other localized sources of cold air in flat terrain, or in a valley that widens at a constant rate, can cause density currents that spread in the radial direction. These have a curved front or head, expanding radially away from a nominal central source. Provided the curvature of the front is not too large, the speed of the front and the fluid behind it are given approximately by eqn [2].

Such flows may be modeled by axisymmetric collapsing bodies of dense fluid, which have some properties that resemble those of one-dimensional spreading. Again, there are three stages of spreading: the slumping, inertial-buoyancy balance, and viscous stages. For a body of dense

fluid of initial height d_0 , radius R_0 , and volume V_0 , in a fluid of overall depth D , the initial collapse occurs in the 'slumping' stage, governed by wave propagation and adverse flow of the ambient fluid. Here the radial position R of the front increases at a constant speed in the range $R_0 < R < R_s$, where R_s corresponds to x_s and denotes the limit of the slumping stage. The shear between the front of dense fluid and the ambient fluid produces vorticity that is initially contained within the mixing head of the current, and as the front expands radially, this vorticity increases by vortex stretching (Figure 4). Downbursts that cause this process may occur on a range of scales – from several hundred meters or more for thunderstorm downbursts, and somewhat less than this for *microbursts*. The latter constitute particular hazards for light aircraft on take-off and landing, because they may create strong localized circular vortices with radii of 100 m or more.

The vortex intensifies as it expands, and initially may be much deeper than the following fluid. For a small initial volume of dense fluid, this expanding vortex ring of dense mixed fluid is all that is produced. But, for a larger initial volume, as the dense fluid expands and the head moves outward, the initial vortex progressively breaks up and is subsumed into the mixed layer. New vorticity is continually created at the head, as for the unidirectional currents, but this is associated with the newly mixed fluid and the stretching is much less than that in the initial vortex. In this second inertial-buoyancy phase (where $R > R_s$), gravity waves maintain approximately uniform depth of the body of dense fluid, and it collapses in the form of an axisymmetric pillbox, with the volume slowly decreasing due to mixing and detrainment behind the circular head. If the volume of dense fluid at any given time is $V = \pi R^2 d_1$, and the properties of the front are given by eqn [2], the radius R increases as

$$R \sim (g'V)^{1/4} t^{1/2} \quad [4]$$

V slowly decreases as dense fluid entering the head is mixed, and this dynamical regime continues until (in the laboratory) the viscous regime is reached.

If the source of dense fluid is maintained with constant volume flux Q_1 , the initial vortex and head form as above but the flow behind it evolves differently, as the depth d_1 and velocity v_1 of the following radial outflow are not uniform and decrease with radial distance r . The only significant mixing

Figure 4 Schematic diagram of the ring vortex shortly after a downdraft reaches the ground.

occurs behind the head, and for steady flow, dimensional analysis gives

$$d_1 \sim \left(\frac{Q_1^2}{g' r^2} \right)^{1/3}, \quad v_1 \sim \left(\frac{Q_1 g'}{r} \right)^{1/3} \quad [5]$$

In the inertio-gravity range, the radial speed of the head is then given by

$$v_H = 0.63 \left(\frac{Q_1 g'}{t} \right)^{1/4} \quad [6]$$

Density Currents Downslopes

When the terrain is not horizontal but slopes downward, buoyancy acts directly to drive the current downward and this is stronger than the indirect effect of establishing a horizontal pressure gradient as described above. The downslope buoyancy force is now $g' \sin \theta$ per unit mass of dense fluid, where θ is the angle between the sloping bottom and the horizontal. The onset of a steady source of dense fluid at the top of the slope leads to the formation of a density current head similar to that described above (see below). In the following current the physics is different, because the flow is now unstable, unless the slope angle is very small. With a homogeneous environment, mixing now occurs along the whole length of the density current, and not just behind the head. After the passage of the head an approximately steady flow is established, with the buoyancy force being balanced primarily by *entrainment* of environmental fluid into the current from above and, to a much lesser extent, by the drag on the bottom surface. Both the size of the head and the thickness of the following current increase with downslope distance.

Behavior of the Head

For a constant supply of dense fluid of buoyancy g'_0 and flow rate Q_0 at the top of the slope, the speed of the head v_H is almost independent of slope angle and is given approximately by

$$v_H = (1.5 \pm 0.2) (g'_0 Q_0)^{1/3}, \quad 5^\circ \leq \theta \leq 90^\circ \quad [7]$$

However, in spite of this uniform speed, the size of the head increases as it moves downslope, at the rate

$$dH/dx = 0.72\theta/\pi \quad [8]$$

where H is the height (or thickness) of the head, x is downslope distance, and θ is in radians. The increased buoyancy at steeper slopes is balanced by increased entrainment that acts to keep the head speed constant, regardless of downslope distance and slope angle.

Entrainment in Downslope Flows into Uniform Environments

After the passage of the head the following flow is unstable to shear instability, and mixing with the overlying fluid results. This process becomes stronger with increasing slope angle θ . The mixed fluid above the dense layer is also denser than the environment, and hence it also moves downslope under gravity

but at a reduced speed. The thickness and volume of this mixed layer both increase with downslope distance. This combined flow may now be regarded as a single entity, and the net downslope buoyancy flux is constant with x and t , and equal to $g'_0 Q_0$. The net entrainment of environmental fluid into this overall downslope flow may be described by an entrainment coefficient E which is a function of the bulk Richardson number Ri , defined by

$$Ri = g' d \cos \theta / U^2 \quad [9]$$

where U is the mean velocity and d the mean thickness of the total flow. At each level, the velocity of inflow w_e of the environmental fluid into the downflow is given by

$$w_e = E(Ri)U \quad [10]$$

where U is the mean velocity of the downflow. E decreases monotonically with increasing Ri , from $E = 0.075$ at $Ri = 0$ to very small values for $Ri > 0.8$. In these flows, Ri is approximately constant with downslope distance, and decreases with increasing slope angle. Experiments show that U , and hence w_e , are also constant, so that the downslope flux Q and the lateral spreading increase linearly with distance. The dynamics of these flows resemble those of plumes of buoyant fluid (from, e.g., chimneys), and are generally referred to as 'plumes.'

Downslope Flows into Stratified Environments

If the environmental fluid is density stratified, the effect of stratification on density currents flowing over a horizontal surface are mostly limited to the generation of internal waves, where the current takes the form of a moving obstacle. However, for flows downslopes, if ambient stratification is present, it is a major parameter. If N is the *buoyancy frequency* of the ambient stratification, one may identify a depth D below the source, defined by $N^2 = g'_0/D$, where the ambient density equals the inflowing density (and g'_0 denotes the buoyancy of the source fluid). If there were no mixing, all of the inflowing fluid would be expected to reach and spread horizontally at this level. The speed of the head is again approximately constant over most of its distance traveled, and scales with [eqn \[7\]](#) above. The main differences from the homogeneous case concern the current following the head, which we next discuss.

There are two main flow regimes that may occur for such downslope currents. These regimes depend on the downslope buoyancy force and the frictional drag of the sloping bottom. If the bottom slope is large enough so that the buoyancy force exceeds the bottom drag, the former must also be (at least partly) balanced by mixing with the overlying fluid. This results in substantial mixing with the environment and entrainment of this mixed fluid into the downslope current, implying inflowing environmental fluid toward the current. This dynamical picture is similar to that with a homogeneous environment as described above – such flows may be regarded as 'plumes,' and as being in the *Plume regime*. This flow is maintained until the density of the downslope current approaches its mean level of neutral density, beyond which it overshoots this level due to inertia, and springs back to settle as an intrusion into the environment around this level.

If instead the bottom slope is small, so that the down-slope buoyancy force is small enough to be balanced by the bottom drag, a different flow regime results. Here the mixing with the environment is small, and the downslope current resembles a gravity current with a distinct upper surface. The mixing that does occur is associated with eddies that mostly lie outside (above) the current, and remove fluid from it in thin filaments. This process has the nature of *detrainment*, whereby fluid leaves the downflow and mixes with the environment, so that, on average, environmental fluid leaves the vicinity of the current, rather than being drawn toward it as in the entrainment case. An example of such flows is shown in Figure 5, and they are said to be in the *Gravity current regime*.

These flows are governed by two dimensionless parameters – a bulk Richardson number Ri defined as in eqn [9] but based on the dense layer only, and a parameter B , the *Buoyancy number*, defined by

$$B = QN^3/g'^2 \quad [11]$$

which is a measure of the effect of the ambient stratification. On theoretical grounds, which are consistent with experiments, the boundary between the two flow regimes is approximately

$$C_D = 0.2B^{0.4} \sin \theta \quad [12]$$

Here if the left-hand side is the larger the flow is in the gravity current regime, and if it is the smaller, the flow is in the plume regime. In principle, since B varies with the flow, the character of the flow may change with distance down the slope.

In the gravity current regime, the dense layer is observed to have approximately uniform thickness over most of its length, but its velocity mostly decreases. It loses fluid to the environment, but also entrains a little fluid from it so that its density progressively decreases, until it reaches its ambient level where it spreads out, at a vertical distance somewhat less than D below the source. Entrainment into this dense layer may be expressed in terms of an entrainment coefficient

Figure 5 The turbulent, mixing interface in the body of a dense layer flowing down a slope at 6° to the horizontal, in a density-stratified environment. The dense fluid is the lightly dyed layer close to the boundary. Note the filaments extending from it, and the detrained mixed fluid above.

that depends on Ri , in a manner similar to eqn [10]. Fluid leaving the dense layer finds its own local neutral level, and this occurs continuously along the path of the current. Dense fluid from the source may therefore be distributed over a range of depths, and not all near one level as in plumes. This *detrainment* into the environment depends on both Ri and B – larger B implies larger detrainment, to the extent that all the dense fluid may be detrained before it reaches its ambient level.

Katabatic Flows Forced by Radiative Cooling

A prominent source of density currents is cooling of air near the ground through radiation. This is a common occurrence at night, particularly under clear skies, and causes drainage flows over uneven terrain. In complex terrain, this can occur at a number of source regions, at different altitudes. Depending on the circumstances, these flows may be quite strong and have depths of several hundred meters, or have speeds of only several meter by second and depths less than 50 m. Nocturnal cooling also tends to reestablish the ambient stratification at low levels that is destroyed by convection during the day. The processes described above can then cause a complex interleaving of stratified layers of air that flow progressively down several slopes, or find their own environmental level, giving flow in various different directions at different heights. Since this occurs at night, good observations of these complex flow patterns are rare.

One region where katabatic flows are common and are reasonably well observed and understood is Antarctica (and to a lesser extent, Greenland), where radiative cooling over the ice sheets sets up a perpetual drainage regime over the whole continent. Cold air produced over the central plateau drains off toward the coast in a layer that is several hundred meters thick, and several degrees colder than the air above. This effect exists throughout the year, and is particularly strong in winter. Speeds increase as the topographic gradient increases toward the coast. Here the intensity of the katabatic flows varies according to the local synoptic situation, but very strong winds of 40 m s^{-1} or more may last for days, or even weeks in certain locations. Near the coast, or up to 50 km out to sea, this shallow, intense (supercritical) air stream may undergo an internal hydraulic jump and adjust to a broader, more slowly moving (subcritical) air stream. These cold offshore katabatic flows may push the ice away from the coast, causing rapid new ice formation in the open water that takes its place, particularly in winter.

Anabatic Flows Forced by Radiative Heating

Daytime radiative solar heating of sloping terrain causes heating of the adjacent air by mixing and convection. This tends to cause flow upslope, although these flows are not as strong as the drainage flows because they depend on lateral gradients for their existence and involve mixing with the overlying fluid. Nonetheless, they are an important part of the diurnal cycle in valley flows influenced by radiative heating and cooling. They may also be important in promoting wild (bush) fire propagation up hillsides.

Convective Storms: Overview

This article is reproduced from previous edition, volume 2, pp 548–559, © 2003, Elsevier Ltd.

Introduction

Convective storms, also commonly referred to as thunderstorms, produce some of the fiercest weather on earth, including flooding rains (with rain rates up to several inches or 100 mm h^{-1}), severe surface winds (sometimes reaching magnitudes greater than 100 kn), hail (reaching the size of grapefruit), frequent lightning, and tornadoes. Individual convective cells are generally observed on scales of $5\text{--}30 \text{ km}$, and can have lifetimes ranging from $30\text{--}40 \text{ min}$ to greater than 6 h . Furthermore, groups of convective cells can become organized into larger mesoscale convective systems, such as squall lines, bow echoes, and mesoscale convective complexes, which can extend over hundreds of kilometers and, in some cases, can last for several days.

Convective storms exist under a wide variety of conditions and evolve in an equally wide variety of ways. Storm behavior is inherently dependent on the environment in which the storm grows, including thermodynamic stability, vertical wind profiles, and mesoscale forcing influences. In the following, the properties of the most basic storm types, including the ordinary cell, multicell, and supercell, are reviewed, and the fundamental physical processes that promote the various storm behaviors are explained. The knowledge of convective storms is based largely on extensive radar studies (using both conventional and Doppler radars) as well as numerical cloud modeling studies. More information on convective storms can

also be obtained from related chapters on lightning, hail, tornadoes, mesoscale convective systems, bow echoes, convective storm modeling, and severe weather forecasting.

Observed Convective Storm Types

The concept of the convective cell is fundamental to a discussion of convective storms. The convective cell will be regarded as a region of strong updraft (greater than 5 m s^{-1}) and associated precipitating downdraft having a horizontal cross section of $10\text{--}100 \text{ km}^2$, and extending in the vertical through most of the troposphere. Intense convective cells can have updrafts greater than 60 m s^{-1} , with downdrafts sometimes greater than 30 m s^{-1} . Research has shown that convective cells as observed on radar often evolve in identifiable, repeatable patterns. On the basis of these radar characteristics, conceptual models have been proposed for the most commonly observed storm types. These include the short-lived ordinary cell, multiple cell systems or 'multicell,' and supercell.

Ordinary Cell Storm

The ordinary cell represents the most basic convective storm type (Figure 1). It consists of a single updraft, which rises rapidly through the troposphere in a conditionally unstable atmosphere, producing large amounts of liquid water and ice.

Figure 1 (a) Towering cumulus stage, (b) mature stage, and (c) dissipating stage of an 'ordinary' convective cell. Courtesy of Doswell, C.A. Adapted with permission from Byers, H.R., Braham, R.R., Jr., 1949. *The Thunderstorm*. Supt of Documents. US Government Printing Office, Washington, DC.

When the raindrops or ice particles become too heavy for the updraft to support, they begin to fall, creating a downdraft that quickly replaces the updraft. The downdraft is initially nearly saturated, but as it falls into the lower troposphere and mixes with drier air, strong evaporational cooling may occur. This cooling accelerates the downdraft (because of negative buoyancy), which spreads out horizontally as a cold pool (gust front) on reaching the surface. If the diverging outflow winds reach severe levels (greater than about 50 kn), the event is referred to as a downburst or microburst. This life cycle (Figure 1) usually takes 30–50 min to complete, and generally severe weather such as high winds or hail tends to be short-lived. Relatively weak, short-lived tornadoes do occasionally occur with ordinary cells, and are sometimes referred to as landspouts or nonsupercell tornadoes.

Multicell Storm

The multicell storm can be thought of as a cluster of short-lived ordinary cells. The cold outflows from each cell, however, combine to form a large gust front, the convergence and lifting along its leading edge being generally strongest in the downshear direction relative to the low-level (0–3 km agl) vertical wind shear vector. In most cases, this also happens to be in the direction of storm motion. This convergence and lifting can trigger new updraft development along and just behind the gust front, and new cells evolve as described in the previous subsection. Figure 2 shows this process in a vertical cross section through a multicellular hailstorm observed during the

National Hail Research Experiment. The new cell growth often appears disorganized, but occasionally occurs on a preferred storm flank. Because of their ability to renew themselves constantly through new cell growth, multicell storms often last many hours, affecting areas of thousands of square kilometers. If the storm motion is very slow, heavy local rainfall may occur, presenting the possibility of flooding. Severe surface winds in the form of downbursts or microbursts can occur with multicell storm systems, with hail and tornadoes also possible in the vicinity of strong updraft centers.

Supercell Storm

The supercell is potentially the most dangerous convective storm, often producing high winds, large hail, and long-lived tornadoes. In its purest form, it consists of a single, quasi-steady, rotating updraft and associated downdraft, which may have a lifetime of several hours. It often evolves from multicell storm systems, and even during its quasi-steady phase may comprise several small-scale rain centers embedded within a larger encompassing cellular structure. However, the general structure and evolution of the supercell suggest that it is dynamically different from ordinary convection.

A schematic of a supercell is presented in Figure 3. Unlike ordinary cells or multicell systems, supercells are often characterized by a persistent separation between the primary updraft and downdraft currents. The updraft region is generally found on the upshear side of the cloud, and is characterized by a well-defined cloud base with rapidly growing cloud turrets above.

Figure 2 Vertical cross section through a multicell hailstorm, along the storm's direction of travel through a series of evolving cells ($n-2$, $n-1$, and n , $n+1$). The solid lines are streamlines of flow relative to the moving system; on the left, their broken ends represent flow into and out of the plane, and on the right, they represent flow remaining within a plane a few kilometers closer to the reader. Light shading represents the extent of the cloud, and the three darker shades represent radar reflectivities of 35, 45, and 50 dBZ. Part V: Synthesis and implications for hail growth and hail suppression. *Monthly Weather Review* 104, 603–610.

Figure 3 Schematic visual view of a mature supercell thunderstorm. Reproduced from Bluestein, H.B., Parks, C.R., 1983. A synoptic and photographic climatology of low-precipitation severe thunderstorms in the southern plains. *Monthly Weather Review* 111, 2034–2046.

This portion of the storm often exhibits pronounced cyclonic rotation. The downdraft region is found primarily downshear of the updraft region, appearing more diffuse due to the heavy precipitation. The anvil spreads predominantly downshear aloft, but in stronger storms also extends upshear somewhat as the divergence near the storm top is able to force itself upstream against the strong upper level flow. Overshooting tops are quite common for the stronger storms. Many supercells also display a stair-step-shaped flanking line extending upshear from the storm's main updraft region. A persistent lowering of the cloud base, referred to as a wall cloud, is also often observed beneath the main updraft region of the storm, and is often a precursor to the development of tornadoes.

The structure of a mature supercell as it might be observed on radar is depicted in Figure 4. The reflectivity field tends to be elongated in the direction of the mean vertical wind shear, with a hooklike appendage often appearing on the southwest flank of the storm. The midlevel reflectivity often overhangs the low-level echo, and often a bounded weak echo region (BWER) appears at middle levels above the edge of the low-level reflectivity gradient. A BWER usually indicates the presence of both strong updraft and strong rotation about a vertical axis in its vicinity.

Figure 5 presents the significant surface features commonly observed during a supercell's mature phase. The main updraft region is found straddling the hook or notch in the rain field, with two primary downdraft regions, referred to the forward flank downdraft (FFD) and rear flank downdraft (RFD), located on the downshear and upshear sides of the updraft, respectively. A surface gust front separates the cool, rainy air from the warm ambient air, with the gust front often wrapped around the southern flank of the storm due to the circulation associated with a surface mesocyclone. This rear-flank gust front can overtake the gust frontal boundary associated with the FFD, creating an occlusion of these frontal features. A tornado, if present, often forms at the tip of this occlusion (on the edge of the hook echo) on the gradient between updraft and downdraft (but within the updraft).

A time series of radar reflectivity structure for a storm that occurred on 19 April 1972 near Norman, OK (Figure 6), portrays a commonly observed trait of supercell storms. About 1 h into the storm's lifetime, the rain center appears to split into two diverging echo masses: the more intense southern storm veers to the right and slows its motion, while the northern storm moves more quickly to the northeast. Such storm splitting is common in association with supercell storms. The right mover (right relative to the direction of the ambient shear vector) is associated with a cyclonically rotating updraft, while the left mover is associated with an anticyclonically rotating updraft. Both right and left movers of a splitting storm are apt to produce severe weather such as hail and high winds, but tornadoes are rarely associated with left-moving (LM) storms.

Physical Mechanisms Controlling Convective Storm Growth and Evolution

Convective storm type and severity are strongly dependent on the environmental conditions in which the storm grows. Of particular importance is the thermodynamic instability (buoyancy) and vertical wind shear. Thermodynamic instability exerts a fundamental control on convective storm strength, as it controls the vertical acceleration of air parcels. Vertical wind shear, however, influences strongly the form that the convection might take, i.e., whether the convection evolves as short-lived ordinary cells, multicells, or supercells. In the following, the basic physical processes that contribute to the wide spectrum of observed convective storm properties are reviewed.

Buoyancy Effects

Convective storms differ dynamically from larger scale atmospheric phenomena primarily due to the much stronger vertical accelerations and resulting vertical motions (both upward and downward) that are produced. Thus, the most fundamental

Figure 4 (Above) Vertical cross section as might be observed on a radar scope during the mature phase of an intense supercell storm. Low-level inflow, updraft, and outflow aloft (solid lines) are superimposed on the radar reflectivity (dashed lines). (Below) Composite tilt sequence. Solid lines are the low-level reflectivity contours, dashed lines outline the echo >20 dBZ derived from the middle level elevation scan, and the black dot is the location of the maximum top from the high-level scan. Adapted from Lemon, L.R., 1980. Severe Thunderstorm Radar Identification Techniques and Warning Criteria. NOAA Technical Memorandum, NWS NSSFC-3, Kansas City, MO (NTIS PB81-234809).

equation relevant to convective storm dynamics is the non-hydrostatic vertical momentum equation:

$$\frac{dw}{dt} = -C_p \bar{\theta}_v \frac{\partial \pi}{\partial z} + B \quad [1]$$

where π is a nondimensional form of the pressure, referred to as the Exner function,

$$\pi \equiv \left(\frac{p}{p_0} \right)^{R_d/C_p} \quad [2]$$

and B is the buoyancy, including the effects of water vapor and precipitation loading:

$$B \equiv g \left[\frac{\theta'}{\bar{\theta}} + 0.61(q_v - \bar{q}_v) - q_c - q_r \right] \quad [3]$$

In these equations, C_p represents the specific heat at constant pressure, p_0 is a reference surface pressure, R_d is gas constant for dry air, θ represents the potential temperature, q_v represents the water vapor mixing ratio, and q_c , q_r , and q_i represent cloud water, rainwater, and ice mixing ratios, respectively.

For an undisturbed environment (e.g., characterized by no variation of wind with height), the pressure contributions to vertical accelerations are usually very small relative to the buoyancy contributions, and are neglected. Under this assumption, an estimate of potential updraft (and downdraft) strength in a convective storm is often made by integrating the potential temperature contributions from buoyancy along a representative parcel path. For an updraft parcel, this quantity

Figure 5 Schematic plan view of a tornadic supercell thunderstorm at the surface. The thick line encompasses radar echo. The thunderstorm wavelike 'gust front' structure is also depicted by the use of a solid line and frontal symbols. Surface positions of the updraft are finely stippled; FFD and RFD are coarsely stippled; and along with associated streamlines (relative to the storm). Likely, tornado locations are shown by encircled T's. The major cyclonic tornado is most probable at the wave apex, while a minor cyclonic tornado may occur at the bulge in the cold front (southern T), which also marks the favored location for new mesocyclone. Anticyclonic tornadoes, if any, are found even farther south along the cold front. Reproduced from Davies-Jones, R.P., 1985. Tornado Dynamics. In: Kessler, E. (Ed.), 1986. Thunderstorms: A Social, Scientific, and Technological Documentary. Vol. 2: Thunderstorm Morphology and Dynamics, second ed. [revised and enlarged]. is referred to as the convective available potential energy (CAPE):

$$\text{CAPE} = \int_{\text{LFC}}^{\text{EL}} g \left(\frac{\theta'(z)}{\bar{\theta}(z)} \right) dz \quad [4]$$

where $\theta'(z)$ defines the potential temperature of a representative adiabatically ascending surface parcel, $\bar{\theta}(z)$ defines the environmental potential temperature profile, and the integral is taken over the vertical interval where the lifted parcel is warmer than its environment (usually from the level of free convection

(LFC) to the equilibrium level (EL)). This calculation is equivalent to evaluating the positive area represented on a skew-T diagram. Maximum potential temperature excesses in convective updrafts can be greater than 10 K, with magnitudes of CAPE larger than $6000 \text{ m}^2 \text{ s}^{-2}$, but generally potential temperature excesses range between 3 and 6 K, with CAPEs of 1500 and $2500 \text{ m}^2 \text{ s}^{-2}$ for moderately unstable convective days. A similar quantity can be calculated for downdraft parcels, and is referred to as DCAPE (downdraft CAPE).

By equating this CAPE (DCAPE) to vertical kinetic energy, one can then estimate the maximum updraft (downdraft) that would be expected from a given environment:

$$W_{\text{max}} = (2 \times \text{CAPE})^{1/2} \quad [5]$$

Using this relationship, a CAPE of $2500 \text{ m}^2 \text{ s}^{-2}$ would translate to a maximum possible updraft strength of 70 m s^{-1} . However, water loading, perturbed vertical pressure gradients, and mixing effects reduce these estimates by roughly 50%. Vertical motions of 60 m s^{-1} or greater have been observed in the strongest storm updrafts, but maximum downdrafts rarely exceed 30 m s^{-1} .

Vertical Wind Shear Effects

While the thermodynamic structure influences strongly the vertical accelerations in a convective storm, vertical wind shear has a strong influence on what form convection might take. In particular, short-lived ordinary cells tend to be the preferred mode of organization in weak wind shear regimes, while multicells and supercells become the respective preferred mode of organization for increasing magnitude of vertical wind shear.

The characteristics of the wind profile in this regard are best represented in the form of a hodograph, where the wind vectors at each height are plotted from the origin, and then the tips of the vectors are connected to produce a hodograph trace (Figure 7). Vertical wind shear vectors are everywhere tangent to this hodograph trace, with the length of the hodograph curve over a given depth being a direct measure of the magnitude of the wind shear over that depth.

Figure 7 Composite hodograph (m s^{-1}) for tornadic supercell storms. Light arrows represent the wind vectors at each level, and heavy arrows indicate the direction of the shear vector at each level (labeled in mbar). The estimated mean storm motion is denoted by an encircled X. Reproduced from Klemp, J.B., 1987. Dynamics of tornadic thunderstorms. Annual Reviews of Fluid Mechanics 19, 369–402. Adapted with permission from Maddox, R.A., 1979. An evaluation of tornado proximity wind and stability data. Monthly Weather Review 104, 133–142.

Figure 8 Typical wind hodographs for (a) ordinary cell, (b) multicell, and (c) supercell storms observed during the Alberta Hail Studies project. Adapted with permission from Chisholm, A.J., Renick, J.H., 1972. The Kinematics of multicell and supercell Alberta hailstorms. Alberta Hail Studies, Research Council of Alberta Hail Studies, Rep. 72-2, Edmonton, Canada, pp. 24–31.

The relationship between wind shear and basic storm type is demonstrated in Figure 8, which depicts composite hodographs from a study of hailstorms in Alberta, showing an increasing length of the hodograph (especially over the lowest 6 km agl) as the type of convection progresses from short-lived storms to supercells. Generally, multicell storms become more prevalent when the length of the hodograph over the lowest 4–6 km agl is greater than 10–15 m s⁻¹, with supercells becoming more prevalent when the length of the hodograph is greater than 20–25 m s⁻¹ over the lowest 4–6 km agl. Also included on the hodograph plots are observed cell motions. For ordinary cells and multiple cell systems, cell motion tends to be with the mean wind over the lower 6–8 km of the profile, appearing on or near the hodograph trace. For the supercell, however, cell motion is well off the hodograph, well to the right of a calculated mean wind from the profile. Similar off-hodograph propagation is evident for the 19 April splitting storm (Figure 6), and reflects the unique dynamic character of supercell storms, as will be described below.

Two physical mechanisms help explain the organizational capacity of vertical wind shear. The first is related to the ability of a cold pool to trigger new convective cells. The second is related to the interaction of an updraft with the environmental vertical wind shear to produce an enhanced, quasi-steady storm structure.

Cold pool–shear interactions

Cold pools are one of the most prominent features of convective storms, and have a critical role in determining whether a storm system can be maintained over a long period of time. This is due primarily to the ability of the cold pool to lift the surrounding air mass, thus serving potentially as a trigger for new convective cells. For a zero wind shear environment, the lifting along the leading edge of a cold pool is generally restricted to the depth of the cold pool's nose, as the circulation generated by the cold pool rapidly drags the lifted air rearward. If the LFC is significantly higher than the nose of the cold pool, then it is unlikely that new cells can be triggered as the cold pool propagates away from a given cell (e.g., Figure 9(a)).

This picture changes significantly with the addition of environmental low-level vertical wind shear. Associated with this vertical wind shear is an opposing circulation that can

Figure 9 Schematics of cold pool–shear interactions. (a) A convective cell in a zero-shear environment produces a cold pool that propagates away from the cell. Without the presence of low-level shear, the circulation of the spreading cold pool inhibits deep lifting, and is less apt to trigger a new convective cell. (b) The presence of low-level shear counteracts the circulation of the cold pool on the downshear side, promoting deeper lifting and an enhanced potential to trigger new convective cells. Adapted from Rotunno, R., Klemp, J.B., Weisman, M.L., 1988. A theory for strong, long-lived squall lines. *Journal of the Atmospheric Sciences* 45, 463–485.

balance the circulation of the cold pool somewhat on its downshear side, producing a more vertically oriented jet of air and deeper lifting at its leading edge (e.g., Figure 9(b)). An 'optimal' state for lifting along the cold pool can be envisioned when the circulation generated by the cold pool matches the opposite circulation associated with the environmental vertical wind shear. The depth/layer of vertical wind shear most important to this process is equivalent to the depth of the cold pool itself, but deeper shear layers will also contribute somewhat to this process. Ambient shear can further enhance the strength of new cells by virtue of the fact that such cells will move downshear along with the cold pool, increasing both the relative inflow into these cells and the time over which the cells maintain their low-level convergence and feed on the warm air ahead of the gust front. All in all, the strength and longevity of multiple cell convective systems are enhanced for increasing magnitudes of ambient vertical wind shear, due primarily to the enhanced ability of the cold pool to trigger new cells.

Updraft-shear interactions

Vertical wind shear can further contribute to convective storm strength, organization, and sustenance through the interaction of the sheared flow with the convective updrafts. These effects can be both positive and negative. The negative effects are most clearly evident during the early stages of a storm's life, as clouds are observed to lean over in the direction of the mean tropospheric shear vector. This process takes vertical kinetic energy out of the accelerating buoyant plume, converting it into horizontal kinetic energy. If the shear is too strong relative to the buoyancy, a cloud can be literally torn apart.

The positive attributes of the shear are most clearly associated with the development of rotation about a vertical axis within the storm. This rotation originates through the tilting of horizontal vorticity inherent in the vertically sheared flow, as can be shown from the vertical vorticity equation:

$$\frac{d\zeta}{dt} = \omega_H \cdot \nabla_H w + \zeta \frac{\partial w}{\partial z} \quad [6]$$

where ω_H and ζ represent the horizontal and vertical components of vorticity, respectively. This process is visualized in Figure 10(a), for an isolated updraft developing in a unidirectionally sheared flow. The updraft initially deforms the ambient vortex lines upward, leading to the development of a vortex couplet at midlevels, centered on the updraft. Cyclonic vorticity is generated on the right flank of the updraft (relative to the direction of the shear vector), with anticyclonic vertical vorticity on the left flank.

The main impact of this rotation on storm structure occurs through the relationship between the velocity field and the pressure field. In particular, the localized development of rotation in a fluid is associated with lowered pressures (e.g., consider what happens when you stir a cup of coffee). For convective scales of motion, this lowering of pressure occurs whether the rotation is cyclonic or anticyclonic. If the resulting rotation at midlevels in a storm is sufficiently strong (e.g., if the storm is developing in a sufficiently sheared environment), the induced pressure deficits at midlevels will produce a significant upward-directed vertical pressure gradient force that will force the updraft to propagate to both flanks of the original cell.

Figure 10 Schematic depicting how a typical vortex tube contained within (westerly) environmental shear is deformed as it interacts with a convective cell (viewed from the southeast). Cylindrical arrows show the direction of cloud-relative airflow, and heavy solid lines represent vortex lines with the sense of rotation indicated by circular arrows. Shaded arrows represent the forcing influences that promote new updraft and downdraft growth. Vertical dashed lines denote regions of precipitation. (a) Initial stage: vortex tube loops into the vertical as it is swept into the updraft. (b) Splitting stage: downdraft forming between the splitting updraft cells tilts vortex tubes downward, producing two vortex pairs. A new updraft is forced on the flanks of the splitting cell in response to upward-directed vertical pressure gradient forcing associated with the midlevel rotation. The barbed line at the surface marks the boundary of the cold air spreading out beneath the storm. Reproduced with permission from Klemm, J.B., 1987. Dynamics of tornadic thunderstorms. *Annual Reviews of Fluid Mechanics* 19, 369–402.

Once the updrafts propagate to the flanks (Figure 10(b)), they become more colocated with the midlevel rotation centers, which are then further enhanced by vortex stretching. The vortex tilting process continues to generate new rotation on the flanks of the storm, and the updrafts will continue to propagate toward these midlevel rotational centers. Thus, the original cell splits into mirror image cyclonic and anticyclonic storms that propagate to the right and left of the shear vector, respectively. This is the most basic process by which supercell storms may be generated and sustained.

The relationship between the velocity and pressure fields in a convective storm can be derived by taking the divergence of the momentum equations, assuming incompressibility, which

leads to the following Poisson equation for the nondimensional pressure, π :

$$\nabla \cdot (C_p \bar{\rho} \nabla \pi) = -\nabla \cdot (\bar{\rho} \mathbf{v} \cdot \nabla \mathbf{v}) + \frac{\partial B}{\partial z} \quad [7]$$

This equation can be solved for the contributions to the perturbation pressure field from the velocity and buoyancy terms on the right-hand side of eqn [7] individually, allowing the vertical momentum eqn [1] to be rewritten to reflect the contributions from velocity-related pressure perturbations and buoyancy-related processes individually as well:

$$\frac{dw}{dt} = C_p \bar{\theta}_v \frac{\partial \pi_{dn}}{\partial z} + \left(-C_p \bar{\theta}_v \frac{\partial \pi_b}{\partial z} + B \right) \quad [8]$$

The first term on the right-hand side of eqn [8] is referred to as the dynamic contribution to vertical acceleration, and includes all the effects of shear on an updraft, such as the initial tendencies for a cell to lean in the direction of the shear as well as the positive influences due to the development of rotation. The second term on the right-hand side of eqn [8] includes the usual effects of buoyancy as well as the compensating effects due to the buoyant contributions to the pressure field. For ordinary convective cells, which develop in weakly sheared environments, the buoyancy terms generally contribute 60–70% of the maximum updraft strength in a storm. However, the supercell storms, which develop in strongly sheared environments, 60–70% of the maximum updraft strength can come from the dynamic contributions, with most of this contribution coming in the lowest several kilometers of the storm. This explains why supercell storms can be unusually strong, and can persist, sometimes even in the presence of significant low-level capping inversions, as are generally observed at night.

The updraft–shear interaction processes described above are symmetric about the ambient shear vector for unidirectionally sheared environments (e.g., shear environments characterized by a straight line on a hodograph). In such cases, mirror image supercells propagating off the hodograph to the right and left of the shear vector can be produced, as demonstrated in idealized cloud model simulations presented in Figure 11(a). This symmetry is modified, however, by the addition of directional shear to the environment. If the environmental vertical wind shear vector turns clockwise with height over the lowest few kilometers agl (referred to as a clockwise-curved hodograph), as presented in Figure 11(b), the pressure forcing is enhanced on the cyclonic flank of the original cell, and a dominant cyclonically rotating supercell results from the original splitting process. However, if the environmental vertical wind shear turns counterclockwise with height (not shown), the anticyclonic member of the original split would have been favored instead. Climatologically, environmental hodographs in the vicinity of supercell storms exhibit cyclonic turning of the shear vector at low levels (e.g., consider the hodographs in Figures 7 and 8(c)), and thus cyclonically rotating supercells tend to be more common and dominant than anticyclonically rotating supercells.

Figure 12 presents the overall flow structure for a mature, cyclonically rotating supercell storm. An anticyclonically rotating supercell is the mirror image of this. The flow vectors depict the main interwoven airstreams, with the low-level flow converging from both ahead and behind of the surface gust front and rising into a deep, rotating updraft, and the midlevel

flow passing in front of and then descending behind the updraft. The updraft reaches the top of the storm, where it then diverges within the anvil, primarily in the downshear direction. While the midlevel rotation in the storm is generated via the tilting of horizontal vorticity associated with the warm, ambient environment (e.g., Figure 10(a)), the air that feeds the low-level rotation originates largely from the cold side of the surface cold pool boundary. Horizontal vorticity is generated in response to the buoyancy gradients across this boundary, as depicted by the low-level vortex lines turning toward the storm on the cold side of the forward flank gust front, and this horizontal vorticity feeds into the low-level updraft in a stream-wise sense, leading to the low-level updraft rotation. It is this low level, rotating updraft that leads to the development of significant tornadoes within supercell storms.

Summary

For convective storms, cold pool generated lifting and dynamic pressure forcing work together to produce the observed storm characteristics. The relative importance of each mechanism is dependent on the characteristics of the thermodynamic profile as well as the vertical wind shear profile of the environment in which the storm grows. A convective system may be composed of both ordinary cells and supercells simultaneously, while maintaining a general multicell character. Storm types also have a tendency to change during the lifetime of an event. For instance, an isolated supercell will often evolve into a more multicellular line of ordinary cells over time as the storm-generated cold pool and associated lifting becomes stronger and begins to dominate over the dynamic lifting effects associated with the rotating updraft. In such cases, a supercell is said to have ‘gusted out’ or ‘lined out.’ Convective storms also change character as they move into a different mesoscale environment, or when they interact with each other, as within a squall line.

While convective updraft characteristics can generally be anticipated quite well from environmental thermodynamic and shear profiles, potential downdraft and resulting cold pool characteristics are much more difficult to gauge from environmental conditions. The storm-generated downdraft and cold pool are certainly sensitive to the amount of thermodynamic instability and the distribution of moisture in the environment, but it is also sensitive to the characteristics of the precipitation that is produced within the storm. For instance, a convective cloud that predominantly produces a few large raindrops or hailstones will tend to have a weaker downdraft and cold pool than a cloud that produces a large quantity of smaller drops, due to decreased evaporation rates. Along these lines, supercell storms have been subclassified into high precipitation (HP), classic, and low precipitation (LP) varieties, based on intensity and distribution of the precipitation and the resulting strength of the system-generated cold pool. Many of these factors are discussed in companion chapters within this volume.

Climatology of Convective Storm Types

Ordinary cell and multicell storm systems are commonly observed from the tropics through midlatitudes, whenever thermodynamic instability exists and there is a sufficient

Figure 11 Plan views of numerically simulated convective storms at 40, 80, and 120 min for two environmental wind profiles (displayed at the upper left) having wind shear between the surface and 7.5 km agl. The storm system in the lower portion of the figure evolves in response to the wind profile for which the vertical wind shear vector turns clockwise with height between the ground and 2.5 km (heavy solid line in the hodograph), while the upper system develops when the shear is unidirectional (same wind profile except follow the heavy dashed line below 2.5 km). The plan view depicts the low-level (1.8 km) rainwater field (similar to radar reflectivity) contoured at 2 g kg^{-1} intervals, the midlevel (4.6 km) updraft (shaded regions), and the location of the surface cold pool boundary (barbed lines). The maximum updraft velocity is labeled (in m s^{-1}) within each updraft at each time. The dashed lines track the path of each updraft center. Arrows on the hodograph indicate the supercell propagation velocities for the unidirectional (dashed) and turning (solid) wind shear profiles. Reproduced from Klemp, J.B., 1987. Dynamics of tornadic thunderstorms. *Annual Reviews of Fluid Mechanics* 19, 369–402.

triggering mechanism for the convection. Supercell storms, however, tend to be more limited to midlatitude, continental regions, where sufficient vertical wind shear can exist in association with thermodynamic instability. Supercell storms are especially prevalent in the spring and early summer in the plains and mid-western regions of the United States, where the Gulf of Mexico supplies a source of low-level moisture to

enhance thermodynamic instability, and the frequent passage of synoptic-scale waves offers a source for the vertical wind shear. The frequency of supercell storms and the associated tornadoes in this part of the United States has led to this region being referred to as ‘Tornado Alley.’

Supercell storms can also be embedded within the rain bands of landfalling tropical storms and hurricanes. These

Figure 12 Three-dimensional schematic view of a mature supercell thunderstorm at a stage when low-level rotation is intensifying. The storm, viewed from the southeast, is evolving in westerly environmental wind shear. The cylindrical arrows depict the flow in and around the storm. The thick lines show the low-level vortex lines, with the sense of rotation indicated by the circular ribbon arrows. The heavy barbed line marks the boundary of the cold air beneath the storm. Reproduced with permission from Klemp, J.B., 1987. Dynamics of tornadic thunderstorms. *Annual Reviews of Fluid Mechanics* 19, 369–402.

supercells tend to be shallower than more classic supercells, as minimal instability ($\text{CAPE} < 1000 \text{ J kg}^{-1}$) is available within the associated tropical air mass. However, very strong low-level vertical wind shears are generated as the rain bands come ashore, and very intense (of order 10 m s^{-1}) updrafts can be generated in the lowest 1–2 km agl in such cells, due to the dynamic vertical pressure gradients associated with the rotating updrafts. Such shallow supercells are hypothesized to be the source of tornado outbreaks within landfalling tropical storms and hurricanes.

In the midlatitudes, convection often occurs in the warm sectors of synoptic-scale waves, in association with cold fronts and warm fronts. In the tropics, convective activity is commonly located along the intertropical convergence zone (ITCZ). In both the tropics and midlatitudes, convection also

commonly occurs along sea breeze fronts or in association with topographic features such as mountain ridges. Generally, oceanic convection tends to be weaker than continental convection, due to less thermodynamic instability over oceanic regions. Convective storms can occur at any time of the day or night, when thermodynamic instability and a trigger are available, but severe convection tends to maximize in the late afternoon and evening hours, in response to the enhanced thermodynamic instability associated with diurnal heating.

Synopsis

Atomic oxygen [O] and atomic hydrogen [H] play fundamental roles in the photochemistry and energetics of the Earth's mesopause region between 80 and 105 km. However, these species are exceptionally difficult to measure and must be inferred from observations of related phenomena. Long-term data sets of these two species exceeding 11 years in length are now available from satellite measurements. These observations reveal the magnitude and variability of [O] and [H], and the 11-year solar cycle is evident in their time series. Radiative and energetic constraints on the [O] concentration show the mesopause region energy balance to be consistent with global annual radiative/chemical equilibrium. This unique data set of atomic species in Earth's atmosphere enables basic tests of the radiant and chemical physics in upper atmosphere climate models.

Introduction

The determination of the abundance of atomic oxygen [O] and atomic hydrogen [H] has long been a central focus in the study of the photochemistry, energy balance, and aeronomy of Earth's mesopause region. Nominally taken to encompass the altitude regime between 80 and 105 km (pressures between 10^{-2} and 10^{-4} hPa), mesopause region density is sufficiently low to enable long-lived populations of H and O, which would otherwise completely react or recombine to form molecular species. Mesopause region atomic oxygen is generated through the photolysis of O₂ at ultraviolet wavelengths, primarily in the Schumann-Runge continuum, the Schumann-Runge bands, and at Lyman- α (121.6 nm) wavelength. Atomic hydrogen is primarily generated by photolysis of H₂O at Lyman- α .

Atomic species O and H play fundamental roles in the energy balance of the mesopause region. They influence both the heating and cooling of the region. Specifically, during the photolysis of O₂ at ultraviolet wavelengths, a substantial fraction of the energy of the absorbed photon is used to break the chemical bond of the O₂ molecule. This energy does not immediately show up as heat but rather is carried away in

chemical potential energy of the two O-atom products of photolysis. Because of the low mesopause region density, recombination of atomic oxygen (to form O₃ or O₂) will occur sometime later, likely at a different location than where the original photon deposition/photolysis occurred. When recombination does occur, the large amount of chemical energy carried by the O-atoms is released, heating the atmosphere. The existence of atomic hydrogen provides a further catalyst for heating of the mesopause region through the highly exothermic reaction of H and O₃ (Mlynczak and Solomon, 1991). This reaction is the single largest source of heat in the mesopause region. In fact, heating by exothermic chemical reactions exceeds that deposited directly by solar radiation throughout much of the mesopause region, as shown in Figure 1 (Mlynczak and Solomon, 1993).

Atomic oxygen also influences the rates of radiative emission by numerous infrared-active molecules in the mesopause region including CO₂, O₃, and OH. Due to the low density in the mesopause region, the vibrational populations of these molecules depart from local thermodynamic equilibrium (LTE) and are said to be in non-LTE. Under non-LTE, the vibrational populations are no longer given by a Boltzmann

Figure 1 Rates of solar heating and heating due to exothermic chemical reactions, illustrating that exothermic reactions are the largest source of heat over much of the mesopause region. After Mlynczak, M.G., Solomon, S., 1993. A detailed evaluation of the heating efficiency in the middle atmosphere. *Journal of Geophysical Research* 98 (D6), 10517–10541. <http://dx.doi.org/10.1029/93JD00315>.

distribution at the local kinetic temperature. Collisions, radiations (both solar and terrestrial), and chemical reactions may determine the vibrational populations under non-LTE. Atomic oxygen in particular is very effective in achieving energy exchange (via collisions) between the translational energy field and the internal vibrational states of CO_2 (Rodgers et al., 1992), O_3 (West et al., 1976), and OH (Kalogerakis et al., 2011). Atomic oxygen is therefore a necessary input to the computation of infrared radiances, fluxes, and cooling rates in the mesopause region.

Knowledge of the atomic oxygen and atomic hydrogen abundances is essential to achieve an understanding of the basic structure and overall composition of the mesopause region. The challenge with measuring atomic oxygen and atomic hydrogen is that neither species has radiative emission features in the mesopause region that can be readily observed from instruments on orbiting satellites. Atomic oxygen has two fine structure lines in the far infrared, one at 63 μm and one at 145 μm . The 63- μm line has been measured from space by the CRISTA instrument carried on the Space Shuttle (Grossman et al., 2000), from suborbital rockets (Grossmann and Vollmann, 1997), and from high altitude balloons (Mlynczak et al., 2004). However, the abundance of atomic oxygen in the thermosphere above is so large that it is not possible to ‘see’ the fine structure emission at the mesopause from an orbiting satellite. Resonance lamp techniques have been used to observe atomic hydrogen from suborbital rockets (Sharp and Kita, 1987).

There is simply no traditional method to observe mesopause region atomic oxygen or atomic hydrogen from orbiting satellites. There are, however, techniques to infer the atomic oxygen and atomic hydrogen concentrations from measurements of ozone and radiative emission from the OH radical (e.g., Good, 1976). The Sounding of the Atmosphere using Broadband Emission Radiometry (SABER) instrument on the NASA Thermosphere-Ionosphere-Mesosphere Energetics and Dynamics (TIMED) satellite has been observing the terrestrial mesosphere and lower thermosphere since January 2002. SABER makes observations of the O_3 abundance and the OH emission at 2.0 μm specifically for the derivation of O and H,

day and night, in the mesopause region. These techniques are discussed below. First, the question of the allowed range of atomic oxygen will be examined. This is essential for understanding the atomic oxygen concentration in general and for providing a basis for validating atomic oxygen concentrations inferred by other means.

Energetically and Radiatively Allowed Range of Atomic Oxygen

Upper Limits on the Atomic Oxygen Concentration

The challenges associated with making direct measurements of atomic oxygen, and the uncertainties associated with inferring it from related measurements, prompt the question as to whether methods exist by which the O concentration can be constrained. Independent validation of measured atomic oxygen is essential because of the importance of O in the energy balance and photochemistry of the mesopause region.

Mlynczak et al. (2013b,c) have presented approaches by which the maximum and minimum vertical profile of global annual mean concentration of atomic oxygen can be determined. These approaches are based on the consideration of global annual mean energy balance and on observations of emission from the highly vibrationally excited hydroxyl (OH) molecule in the mesopause region, the latter analyzed in the limit of complete radiative deactivation. These approaches place fundamental constraints on the maximum and minimum global annual mean atomic oxygen concentration independent of the standard techniques used to derive and infer the atomic oxygen concentration.

The first approach proceeds from considerations of energy balance and the role that exothermic chemical reactions play in the heat budget of the mesopause region. Following Mlynczak et al. (2013b), the global annual mean, energy balance at a given altitude or pressure level in the mesopause region can be written as:

$$H(\text{O}_2) + H(\text{O}_3) + H(\text{C}) + H(\text{D}) = C(\text{IR}) \quad [1]$$

In eqn [1], $H(\text{O}_2)$ and $H(\text{O}_3)$ are the rates of heating due to the absorption of solar ultraviolet radiation by O_2 and O_3 , $H(\text{C})$ is the heating due to exothermic chemical reactions, $H(\text{D})$ is the heating rate due to dynamical processes such as gravity wave breaking, and $C(\text{IR})$ is the rate of radiative cooling due to infrared (IR) emission. Equation [1] neglects some small heating and cooling terms such as heating due to absorption of near-IR solar radiation by CO_2 and cooling by emission of infrared radiation by H_2O . These small terms are of comparable magnitude and are neglected as they do not influence the derivation of the radiatively constrained atomic oxygen.

To proceed, two points are noted. First, the heating due to exothermic chemical reactions $H(\text{C})$ and the heating due to absorption of solar ultraviolet radiation by ozone $H(\text{O}_3)$ can be expressed as functions of atomic oxygen. Equation [1] can be rewritten, neglecting $H(\text{D})$, as:

$$F(\text{O}) = C(\text{IR}) - H(\text{O}_2) \quad [2]$$

Here, $F(\text{O})$ represents the functional form of the sum of $H(\text{O}_3)$ and $H(\text{C})$ that is only a function of atomic oxygen. As shown in Mlynczak et al. (2013b), $F(\text{O})$ is a simple quadratic

equation whose coefficients depend only on standard reaction rate coefficients and enthalpies. The second point is that by neglecting $H(D)$, the O derived from eqn [2] represents an upper, radiatively allowed limit of atomic oxygen, constrained by the rates of radiative cooling by CO_2 and solar heating due to absorption by O_2 . The radiatively constrained atomic oxygen derived from $F(O)$ is independent of any of the standard techniques used to infer atomic oxygen that are discussed below. As such it not only represents an upper limit on the global annual mean atomic oxygen concentration in the mesopause region, but it also serves as an independent validation of the global mean atomic oxygen derived by other methods. The true atomic oxygen cannot be larger than that derived from eqn [2]. Otherwise, the $H(C)$ term would be too large and the mesopause region would perpetually warm due to the heat deposited from exothermic chemical reactions.

Equation [2] is evaluated using standard SABER data products of carbon dioxide radiative cooling rates and heating rates due to absorption of ultraviolet radiation by O_2 , as given in Mlynczak et al. (2013b). Figure 2 shows the radiatively constrained global annual mean atomic oxygen concentration derived from SABER for 2004 and 2008. The concentrations decrease from 2004 to 2008 due to the declining solar cycle over those years. Peak, radiatively allowed atomic oxygen concentrations near 95 km are approximately $5 \times 10^{11} \text{ cm}^{-3}$.

Lower Limits on the Atomic Oxygen Concentration

A technique for determining a radiatively allowed lower limit on the global annual mean atomic oxygen concentration will now be reviewed, following Mlynczak et al. (2013c). At night, the OH radical is produced by the reaction of H and O_3 , which is very exothermic, and produces highly vibrationally excited OH up to the $v = 9$ state. The OH molecule radiates strongly, particularly in the infrared, where the radiative lifetime of the highest lying vibrational states ($v = 8$ and $v = 9$) is about 8 ms.

Figure 2 Global annual mean radiatively constrained atomic oxygen concentration profiles derived from SABER for 2004 and 2008. After Mlynczak, M.G., et al., 2013b. Radiative and energetic constraints on the global annual mean atomic oxygen concentration in the mesopause region. *Journal of Geophysical Research – Atmospheres* 118, 5796–5802. <http://dx.doi.org/10.1002/jgrd.50400>.

These highly vibrationally excited states are also physically quenched in collisions with O_2 , N_2 , and even O . Assuming photochemical equilibrium between the production of ozone by recombination of O and O_2 , and loss of ozone by reaction of H and O_3 , a relatively simple relation between the observed emission rate of highly vibrationally excited $OH(v)$, the rates of loss of $OH(v)$ by collisions and radiation, and the atomic oxygen concentration is established. This is the basic technique employed by SABER for deriving the atomic oxygen concentration at night from measurements of $OH(v)$ emission in a channel near $2 \mu\text{m}$ (Mlynczak et al., 2013a).

The observed rate of $OH(v)$ emission depends on three factors: the atomic oxygen concentration, the rate of spontaneous emission of radiation by the $OH(v)$, and the rate at which collisions between $OH(v)$ and other species quench the vibrational states to lower vibrational levels including the ground state, or cause reaction and loss altogether of the $OH(v)$. The rates of spontaneous emission, given by the Einstein A coefficients for each transition, are fixed – an excited state will always attempt to radiate with a lifetime specified by the A coefficient. However, for an observed $OH(v)$ emission rate, the derived atomic oxygen depends directly on the rates of quenching of the $OH(v)$ by collisions with O_2 , N_2 , and O . Specifically, the derived O is proportional to the strength of quenching for a specific observed $OH(v)$. Higher rates of collisional quenching require more atomic oxygen and vice versa. In the limit of no collisional quenching, in which the $OH(v)$ is assumed to relax solely by the spontaneous emission of radiation, the minimum atomic oxygen concentration will be derived.

Mlynczak et al. (2013c) applied this principle to the SABER observations of $OH(v)$ at night in order to derive a radiatively

Figure 3 Minimum (blue curves) and maximum (red curves) radiatively allowed atomic oxygen concentrations for 2004 and 2008, derived from SABER. After Mlynczak, M.G., et al., 2013b. Radiative and energetic constraints on the global annual mean atomic oxygen concentration in the mesopause region. *J. Geophys. Res. Atmos.* 118, 5796–5802. <http://dx.doi.org/10.1002/jgrd.50400>; Mlynczak, M.G., Hunt, L.A., Marshall, B.T., Mertens, C.J., Russell III, J.M., Siskind, D., Thompson, R.E., Gordley, L.L., 2013c. Radiative constraints on the minimum atomic oxygen concentration in the mesopause region. *Geophysical Research Letters* 40, 3777–3780. <http://dx.doi.org/10.1002/grl.50725>.

constrained minimum atomic oxygen profile in the mesopause region. **Figure 3** shows the minimum radiatively allowed atomic oxygen (blue curves) along with the maximum radiatively allowed atomic oxygen (red curves), for the years 2004 and 2008. These are the global annual mean values in both the cases. The true global annual mean atomic oxygen concentration must fall between the blue and the red curves.

The peak minimum atomic oxygen concentrations shown in **Figure 3** near 95 km are about $3 \times 10^{11} \text{ cm}^{-3}$. This value is only about 40% smaller than the radiatively allowed maximum atomic oxygen. The conclusion is that the allowed range of global annual mean atomic oxygen is rather small, about 3×10^{11} to $5 \times 10^{11} \text{ cm}^{-3}$ at the peak. This result places fundamental limitations on the chemistry and energetics in numerical models of the middle and upper atmosphere. It also brackets the range for observations of the atomic oxygen concentration, which will now be discussed in detail.

Derivation of Atomic Oxygen from Measurements of OH(ν) and O₃

The results presented in Section [Energetically and Radiatively Allowed Range of Atomic Oxygen](#) effectively bracket the range of allowed values of the global annual mean vertical profile of atomic oxygen in the mesopause region. In this section, the approach for deriving atomic oxygen from related measurements will be given. Because the lifetime of atomic oxygen is long (approximately days to weeks) in the mesopause region, derivations of O both day and night are required. To this end, the SABER experiment was designed to derive atomic oxygen day and night, using different approaches for each, which are described in detail by [Mlynczak et al. \(2013a\)](#). These are now summarized briefly here.

For the day, photochemical equilibrium between production of ozone by recombination of O and O₂ is taken to be in balance with destruction of ozone by ultraviolet photolysis. Specifically,

$$J[\text{O}_3] = k_2[\text{O}][\text{O}_2][M] \quad [3]$$

In [eqn \[3\]](#), J is the photolysis rate (s^{-1}) of ozone, primarily entirely in the Hartley band from approximately 200 to 350 nm, M is the total number density (cm^{-3}), and k_2 is the recombination rate coefficient ($\text{cm}^6 \text{ s}^{-1}$).

For night, SABER measurements of the OH emission near 2.0 μm are used to derive O. SABER observes the $\nu = 8$ and $\nu = 9$ states of OH ([Mast et al., 2013](#)) that are formed directly upon reaction of H and O₃ to derive the atomic oxygen concentration. At night, production of ozone by recombination of O and O₂ is balanced by the loss of ozone by reaction of H and O₃. The photochemical balance for this process is written as:

$$k_4[\text{H}][\text{O}_3] = k_2[\text{O}][\text{O}_2][M] \quad [4]$$

where k_4 is the reaction rate coefficient of H and O₃. The notations k_4 and k_2 are used for consistency with [Mlynczak et al. \(2013a\)](#). The product $k_4[\text{H}][\text{O}_3]$ is directly related to the

observed rate of emission from the OH ($\nu = 8, 9$) states, which enables the O atom concentration to be derived directly from measurements of the OH(ν) emission. The O₂ and the total number densities are derived from SABER measurements of pressure and temperature. This technique for derivation of atomic oxygen was developed by [Good \(1976\)](#).

Derivation of Atomic Hydrogen from Measurements of OH(ν)

SABER measurements of the OH(ν) emission rate and of ozone can be used to derive the atomic hydrogen concentration at night. Once the atomic oxygen concentration is derived from [eqn \[4\]](#), this equation is used to directly solve for H by back substitution of the derived O into the right-hand side of the equation. SABER measurements of emission from ozone at 9.6 μm are used to provide the O₃ concentration on the left-hand side of [eqn \[4\]](#). SABER temperature and pressure data are used to compute the total number density and to compute the temperature dependence of the rate coefficients k_2 and k_4 , allowing [eqn \[4\]](#) to be solved directly for the H concentration. The SABER approach also follows directly from [Good \(1976\)](#).

Observations of Atomic Oxygen and Atomic Hydrogen

In this section, we present observations of the O and H atoms derived from SABER observations as discussed above. Zonal annual and global annual means are given because of the importance of these species in the mesopause region energy balance, and the strictest test in this regard is the global annual mean value ([Mlynczak et al., 2013b](#)). The SABER atomic oxygen and atomic hydrogen data are however available on a profile-by-profile basis, approximately 1500 profiles per day, since January 2002. The excellent precision (low radiometric noise) of the SABER radiometer ([Mlynczak et al., 2013a](#)) enables retrieval of O and H for each individual limb radiance profile measured by the instrument. The individual species vertical profiles are of high quality and may be used to study the atomic species in the mesopause region on daily and longer timescales. These data are publicly available via the link to the SABER data website given at the end of this article.

Day Atomic Oxygen

Shown in **Figure 4** are SABER day zonal annual mean atomic oxygen concentrations (left panels) and SABER day zonal annual mean volume mixing ratios (right panels) for the years 2002, 2008, and 2012. These years span the time from near the maximum to the minimum of solar cycle 23 (2002–08) and well into the rise into solar cycle 24 (2012). The volume mixing ratios are the base 10 logarithm of the actual mixing ratio due to the range of mixing ratio (three orders of magnitude) encountered in the mesopause region. Both the concentrations and mixing ratios are largely zonally symmetric in the day. Peak atomic oxygen concentrations in

Figure 4 Day zonal annual mean atomic oxygen concentrations (cm^{-3} , left panels) and volume mixing ratios (right panels) for 2002, 2008, and 2012. Mixing ratios are base 10 logarithm of the actual volume mixing ratio. Day atomic oxygen derived from measurements of the ozone concentration. After Mlynarczyk, M.G., et al., 2013a. Atomic oxygen in the mesosphere and lower thermosphere derived from SABER: algorithm theoretical basis and measurement uncertainty. *Journal of Geophysical Research – Atmospheres* 118, 5724–5735. <http://dx.doi.org/10.1002/jgrd.50401>.

excess of $6 \times 10^{11} \text{ cm}^{-3}$ are observed near 95 km in 2002 and 2012. The observed peak concentrations in 2008 are smaller by $\sim 20\%$, and are likely a result of the occurrence of solar minimum during that time.

Figure 5 shows the day global annual mean atomic oxygen concentrations for 2002, 2008, and 2012 derived from the zonal mean values in Figure 4. The variability in day atomic oxygen is clearly evident with the 2008 global annual mean

peak concentration approximately 20% smaller than in 2002 and approximately 10% smaller than in 2012. The progression of the solar cycle is clearly illustrated in Figure 6, which shows the difference in the day global annual mean atomic oxygen concentration in each year from that in 2002. The values are negative indicating that the day global annual mean atomic oxygen is smaller each year after 2002. The largest differences occur in 2008–09 during solar minimum conditions.

Figure 5 Day global annual mean atomic oxygen concentrations (cm^{-3}) for 2002, 2008, and 2012. Minimum concentrations occur in 2008 during the time period associated with a minimum of solar activity.

Night Atomic Oxygen

Figure 7 shows the night zonal annual mean atomic oxygen concentrations (left panels) and (base 10 logarithm) volume mixing ratios (right panels) for 2002, 2008, and 2012. The night atomic oxygen concentration exhibits a much different spatial pattern than in the day, with maxima occurring in each hemisphere near 35° latitude. This pattern may be associated with tidal activity. The night volume mixing ratios also exhibit variations with latitude, unlike the day values, which are also suggestive of a tidal origin. Nevertheless, the day and night atomic oxygen concentrations are quite similar, especially in the global mean, as noted by Mlynarczyk et al. (2013a). The concordance of the day and night concentrations, in the annual means, is remarkable, given the two disparate techniques (and

associated assumptions and parameters) used in their derivation.

Figure 8 shows the global annual mean atomic oxygen concentrations at night for 2002, 2008, and 2012. As with the day concentrations, night minimum occurs in 2008, and the relative values in 2002 and 2012 are also consistent with the day. Figure 9 shows the difference in the night global annual mean atomic oxygen concentration from 2002 for each year from 2003 to 2012. The values (as in Figure 6) are negative, indicating that the night atomic oxygen is also smaller in all years after 2002. The largest difference is again seen to occur in 2008. Of particular interest is that the differences at night in the global annual mean atomic oxygen concentration are only about one-half the magnitude of those in the day shown in Figure 6. This result suggests that the influence of the solar cycle may be different during the day than at night. In particular, since atomic oxygen is subject to dynamical transport, these results suggest that solar activity influences both the chemistry and the dynamics, resulting in a different ‘solar cycle’ response of atomic oxygen for day and for night.

Comparison between Derived and Radiatively Constrained Atomic Oxygen

The SABER atomic oxygen data set is unique in its length and in the agreement between the day and the night atomic oxygen derived from two different techniques. In this section, the SABER-derived atomic oxygen is compared with the radiatively allowed atomic oxygen concentrations given earlier. The purpose is to provide a measure of validation of the SABER-derived atomic oxygen and to place the derived abundance in context with the global annual mean energy balance of the mesopause region.

Shown in Figure 10 are the SABER global annual mean atomic oxygen concentrations (average of day and night values, labeled ‘SABER’), along with the radiatively constrained

Figure 6 Time series of the difference in the global annual mean atomic oxygen concentration from 2002 through 2012. This figure shows the progression of the solar cycle in the daytime. Negative contour values indicate a decrease of atomic oxygen from 2002.

Figure 7 Night zonal annual mean atomic oxygen concentrations (cm^{-3} , left panels) and volume mixing ratios (right panels) for 2002, 2008, and 2012. Mixing ratios are the base 10 logarithm of the actual volume mixing ratio. Night atomic oxygen derived from measurements of $\text{OH}(v)$. After Mlynczak, M.G., et al., 2013a. Atomic oxygen in the mesosphere and lower thermosphere derived from SABER: algorithm theoretical basis and measurement uncertainty. *Journal of Geophysical Research – Atmospheres* 118, 5724–5735. <http://dx.doi.org/10.1002/jgrd.50401>.

minimum (labeled 'RC min') and maximum concentrations (labeled 'RC max'), for the year 2012. The SABER-derived atomic oxygen is much closer to the maximum allowed radiative constrained values than to the minimum allowed values. Above 92 km, the SABER values are approximately 15% larger than the maximum allowed radiatively constrained atomic

oxygen. The pattern is observed for all years although only 2012 is shown here. The uncertainty in both the SABER-derived and the maximum radiative constrained values is $\sim 20\%$ (Mlynczak et al., 2013a,b), so in essence, the SABER atomic oxygen agrees with the maximum radiative constrained atomic oxygen throughout the mesopause region.

Figure 8 Night global annual mean atomic oxygen concentrations (cm^{-3}) for 2002, 2008, and 2012. Minimum night atomic oxygen occurs in 2008 during a period of minimum solar activity.

There is one major consequence of the SABER atomic oxygen concentrations at the global mean values shown in [Figure 10](#). Specifically, the data imply that the global annual mean mesosphere is near radiative/chemical equilibrium, and that heating or cooling due to dynamical processes such as gravity wave breaking are minimal in the global annual mean. This is because the *maximum* radiatively constrained atomic oxygen is consistent with the difference between radiative cooling by carbon dioxide and solar heating associated with molecular oxygen. However, as discussed in [Mlynczak et al. \(2013a\)](#), the uncertainty in the SABER-derived atomic oxygen concentration is $\sim 20\%$, and by inference, so is the global mean heating rate due to exothermic chemical reactions and absorption of solar ultraviolet radiation by ozone. This uncertainty leaves substantial room for other processes such as turbulent dissipation of breaking gravity waves to be a significant component of the global mesopause region energy budget,

Figure 10 Comparison of SABER global annual mean atomic oxygen concentrations (day and night average) with radiatively constrained maximum (RC max) and radiatively constrained minimum (RC min) concentrations for 2012. After Mlynczak, M.G., et al., 2013b. Radiative and energetic constraints on the global annual mean atomic oxygen concentration in the mesopause region. *J. Geophys. Res. Atmos.* 118, 5796–5802. <http://dx.doi.org/10.1002/jgrd.50400>; Mlynczak, M.G., Hunt, L.A., Marshall, B.T., Mertens, C.J., Russell III, J.M., Siskind, D., Thompson, R.E., Gordley, L.L., 2013c. Radiative constraints on the minimum atomic oxygen concentration in the mesopause region. *Geophysical Research Letters* 40, 3777–3780. <http://dx.doi.org/10.1002/grl.50725>.

and remains the single largest uncertainty in quantifying the energy balance of the mesopause region. Atomic oxygen may need to be known to be better than 10% in order to further improve and quantify the role of dynamical processes on the mesopause region energy budget.

Night Atomic Hydrogen

Shown in [Figure 11](#) (left panels) are the night zonal annual mean concentrations of atomic hydrogen derived from SABER

Figure 9 Time series of the difference in the global annual mean atomic oxygen concentration from 2002 through 2012. This figure shows the progression of the solar cycle at night. Peak concentration differences at night are approximately half of that during daytime (see [Figure 6](#)).

Figure 11 SABER-derived night zonal annual mean atomic hydrogen concentrations (cm^{-3} , left panels) and volume mixing ratios (parts per million, right panels) for 2002, 2008, and 2012.

for the years 2002, 2008, and 2012. The concentrations are in units of 10^8 cm^{-3} . The night H exhibits a peak concentration of $\sim 2.6 \times 10^8 \text{ cm}^{-3}$ in the lower part of the mesopause region around 84–85 km. Above 87 km, the H concentration is relatively uniform with latitude and continually decreases with altitude. The right panels of Figure 11 show the volume mixing ratio of H in parts per million. The mixing ratio is observed to increase with altitude, and is largest near the equator on a given pressure surface.

Figure 12 shows the night global annual mean H concentrations for 2002, 2008, and 2012. In contrast to atomic oxygen, the global annual mean atomic hydrogen concentrations are observed to *increase* from 2002 to 2008, and *decrease* from 2008 to 2012, i.e., directly out of phase with the solar cycle during this time. This is further evident in Figure 13 in which the time series of the difference in the night global annual mean H concentration for each year from that in 2002. In particular, there is about a 15% increase in the global annual

Figure 12 SABER-derived night global annual mean atomic hydrogen concentrations (cm^{-3}) for 2002, 2008, and 2012. Concentrations in 2008 are largest despite occurring during the time of minimal solar activity.

Figure 13 Time series of the difference in the SABER-derived global annual mean atomic hydrogen concentration from 2002 through 2012. This figure shows the progression of the solar cycle at night. Positive values indicate an increase in atomic hydrogen from 2002, peaking during 2008–09, which corresponds to solar minimum conditions.

H concentration from 2002 to 2009 at ~ 87 km altitude. Other SABER parameters such as O_3 and temperature, in addition to atomic oxygen, are positively correlated with the solar cycle, but H is not. This effect of increasing H with decreasing solar activity has also been observed in data from the SCIAMACHY experiment (Kaufmann et al., 2013).

Summary and Future Directions

The SABER data set of atomic oxygen and atomic hydrogen now covers nearly 12 years in length, starting from January 2002. It is presently the longest continuous set of observations of atomic species in the mesopause region. The TIMED mission has been approved for operations until at least September 2015, with

possibility for extension beyond that date. The SABER atomic species data begin near solar maximum in 2002, continue through the prolonged solar minimum in 2008, and go well into the onset and progression of solar cycle 24. Over 6 million individual profiles of atomic oxygen and atomic hydrogen are now stored on the SABER data server for scientific research.

The SABER data have also been used to provide fundamental new understanding of atomic oxygen concentrations in the mesopause region. The concept of radiatively allowed global annual mean maximum and minimum atomic oxygen concentration profiles now provides fundamental limits within which observed and modeled atomic oxygen concentrations must fall (Mlynczak et al., 2013b,c). The range is surprisingly narrow, with roughly a 40% difference between the maximum and minimum allowed peak atomic oxygen concentration. Prior to these concepts there was no direct way to validate or constrain modeled or observed values of atomic oxygen.

A major issue going forward is resolving the energy balance of the mesopause region, which is a key motivation and focus of the SABER experiment on the TIMED mission (Mlynczak, 1997). The uncertainty in atomic oxygen is a limiting factor in resolving the relative roles of chemical heating, solar heating, and dynamical heating in the mesopause region. The SABER data are consistent with a mesopause region near global mean radiative/chemical equilibrium due to the agreement between the SABER-derived atomic oxygen and the maximum radiatively constrained atomic oxygen. Uncertainties in the derived atomic oxygen presently preclude a more definitive conclusion. However, the accuracy of SABER atomic oxygen can be substantially improved if the uncertainty in the rate coefficient for the recombination of O and O_2 can be reduced. At mesospheric temperatures, this rate coefficient carries an uncertainty in excess of 20% and is the primary source of uncertainty in deriving the atomic oxygen concentrations from O_3 and $\text{OH}(v)$ and the radiative constrained values of atomic oxygen (Mlynczak et al., 2013a,b,c).

SABER atomic hydrogen data provide a previously unseen look into the long-term evolution of the mesopause region. The anticorrelation of atomic hydrogen with the solar cycle likely originates from a dynamical or thermal cause. It cannot be due to variability in solar radiation as the solar Ly- α irradiance decreases markedly over the solar cycle. Additional study with the combined SABER data set including the thermal structure, ozone, atomic species, and energetics will likely reveal the mechanism resulting in an increasing H concentration with decreasing solar activity.

The data presented above are unique for the length of the data set and for the radiometric quality that has resulted in over 6 million individual profiles of atomic oxygen and atomic hydrogen to be generated to date. Because of the central role atomic species have in the mesopause region energy budget, these data can provide fundamental assessments of the radiant and chemical physics of upper atmosphere climate and general circulation models. The concept of radiatively constrained atomic species further complements these data by providing independent means of validating the highly derived species abundances. The SABER team looks forward to extending the data set as long as possible for assessment of potential changes in atmospheric composition and energetics associated with climate change.

Acknowledgment

The authors would like to thank the National Aeronautics and Space Administration for the continued support through the TIMED mission and the SABER project, as well as through the Living with a Star and Heliophysics Guest Investigator Programs. All SABER data are freely available for download over the World Wide Web at www.saber.gats-inc.com.

Synopsis

This article provides an overview of the ionosphere with an introduction to early understanding of the elements and discussion of its sources and fundamental features. The article also discusses the different latitudes of the ionosphere and its relevance to space weather and as an earthquake predictor.

Introduction

The early Greeks thought that all material was created from four elements: air, earth, fire, and water. We now know that the elements are actually combinations of protons, neutrons, and electrons and that all matter is made from various combinations of these atomic building blocks. However, when cataloging the possible *states* of matter, the ancients were not so far off. In our daily lives, the states of matter referred to as solid, liquid, and gas are clearly related to Aristotle's earth, water, and air.

But what about fire? What about a fourth state of matter? Indeed, there is a fourth state of matter, the state called 'plasma,' which could equally well have been called 'fire,' since the hotter a flame, the closer it comes to the plasma state. We dwell here for a moment on the plasma state itself, since the earth is surrounded by just such a medium – a region called the ionosphere – which is the topic of this section. In fact, we see throughout this volume that the atmosphere of the earth itself includes all four states of matter when one includes raindrops, snow, ice, and the ionospheric plasma, in addition to the gaseous component.

The list of earth, water, and air (solid, liquid, and gas) can be reordered according to the common knowledge that when a solid is heated, it becomes a liquid and then a gas in processes called 'change of phase.' At each phase change, bonds are broken to form the next phase. More energy is required at each step and, by the time one gets to the transition from gas to plasma, quite a lot of energy is required. In this final step, the phase change required actually rips an electron away from the gaseous atom or molecule, leaving a positive ion behind. Since electric charge is conserved, the new state of matter remains neutrally charged on average (equal numbers of positive ions and negative electrons), but these constituents may seldom run into each other and hence have little chance to recombine into the atomic (gaseous) state, and thus, a plasma is born.

How much energy is needed to rip apart atoms? The response is 'a few electron volts,' which is surprising at first, since we are all familiar with batteries in our radios and automobiles that operate at voltages of 1.5–12 V. But we must remember that batteries run on chemical reactions, which themselves involve exchanges of electrons between atoms and molecules, so the volt is a natural-sized unit for ionic bonds. How can we relate this unit to temperature? Suppose we have a pure gas like hydrogen; how hot must it be to become a plasma? Suppose the gas is already hot enough for H₂ molecules to separate into pure hydrogen as the bonds are broken due to collisions with each other. The proton–electron pair that makes up a hydrogen molecule has a bond requiring

13.5 electron volts to break. So for significant numbers of atom collisions to result in ionization, e.g.,

the average energy of the colliding H atoms must be the order of 13.5 electron volts. What does a volt mean? The unit of a volt is Joules per Coulomb (J C^{−1}). This means that if a 1-volt battery is capable of storing one Coulomb of charge, a total of 1 J of energy is available (enough to lift 1 kg 1 m on the earth's surface). A typical car battery can supply 100 A (100 C s^{−1}) for 1 h, so it stores about 360 000 C. Thus, the 12-V car battery stores about 4.3 million Joules (12 J C^{−1} 360 000 C), enough energy to lift a 1000 kg car to a height of 430 m. You should respect your car battery. Since an electron has only 1.6 × 10^{−19} C, 13.5 electron volts corresponds to about 2.2 × 10^{−18} J. Now we need to relate energy to temperature. Kinetic theory shows that the average energy of a particle in a gas is equal to (3/2)*k_BT*, where *k_B* is Boltzmann's constant (1.38 × 10^{−23} J deg^{−1}) and *T* is the absolute temperature in degrees Kelvin. If we set this expression equal to 2.2 × 10^{−18} J and solve for *T*, we find 106 280 K. Such a high temperature shows why it is difficult to produce and control plasmas in laboratories or fusion machines.

The sun is powered by nuclear fusion at its core and is therefore very hot; hence it follows that much of its matter is ionized. Gravity controls this fiercely hot object. The earth is much cooler, of course, and hence it is not obvious that a plasma state would exist in its environs. However, a plasma surrounds the earth, called the ionosphere. The fundamental production and loss mechanisms for the earth's ionosphere are described next, followed by more exotic sources of the plasma surrounding the earth, including the solar wind, magnetic storms, meteors, and the aurora. These sources are localized in time and space and can be linked under the umbrella of weather processes in space or, in short, space weather. Space weather is also influenced by sources of energy and momentum from the earth, the dense atmosphere below, and sources including waves from severe storms, orographic features, and earthquakes, as well as the release of stored energy via plasma instabilities.

Sources and Fundamental Features of the Ionosphere

The ionosphere is formed primarily when the most intense component of the solar spectrum – the X-rays and extreme ultraviolet (EUV) light – impacts the illuminated side of the earth. These high-energy photons strike the dayside of the earth, ionizing the upper atmosphere and losing energy in

the process. As the beam penetrates the atmosphere, the ionizing beam becomes weaker and weaker, leaving behind a layer of ionization. Part of the energy goes into heat as well as into ionizing the air, resulting in the temperature also rising to values much higher than in any part of the dense atmosphere below. Life on earth is thus protected by its upper atmosphere from these dangerous photons, just as the ozone layer absorbs the lower energy, but still harmful, ultraviolet component of the sun's spectrum.

We compare and contrast the atmosphere and ionosphere in Figure 1. The most important atmospheric parameter is temperature, which we plot vs height on the left. The key ionospheric parameter is the number of electrons (which equals the number of positive ions) per cubic centimeter. This is plotted on the right for typical nighttime and daytime conditions.

As anticipated above, the atmospheric temperature rises from its lowest value near the mesopause (near 200 K) to well over 1000 K in the thermosphere in the same height range where the daytime ionosphere is produced. A glance at the right hand side of Figure 1 shows that the ionosphere does not entirely disappear at night, even though the sunlight is no longer present to create new ionization. This is one of the key characteristics of the earth's ionosphere and explains, for example, how Marconi was first able to send wireless signals across the Atlantic Ocean at night.

To understand why some of the ionosphere remains through the night, we must consider the ion chemistry of the region.

At high altitudes (>300 km), production (P) and loss (L) of ionospheric plasma are both small. The result is a balance between diffusion and gravitation and results in the so-called hydrostatic equilibrium in which the plasma pressure (p) is of the form

$$p = p_0 e^{-h/H_p} \quad [1]$$

where 'e' is the base of the natural logarithms, h is height above some reference, p_0 is the pressure at the reference altitude, and H_p is the plasma scale height,

$$H_p = \frac{k_B T}{(M/2)g} = \frac{2k_B T}{Mg} \quad [2]$$

In eqn [2], M is the average ion mass and g is the gravitational acceleration. Equation [1] says that the pressure falls by a factor of about 2.7 with every altitude increase of H_p . M is quite close to the average mass of the neutral atmospheric particles surrounding the plasma. The factor of 2 comes from the average *plasma* mass being half the ion mass, since the electron mass is so tiny. The neutral atmosphere behaves like [1] except the neutral scale height, H_n , is half as large. We conclude that because the electrons are so light, the ionosphere extends higher into space than the neutral atmosphere surrounding it. For reference, H_n is about 50 km and H_p is about 100 km in the middle ionosphere.

At these altitudes, the composition of the atmosphere is no longer similar to the surface composition (79% N_2 , 20% O_2 + minor constituents). The atmosphere is no longer mixed, and lighter atoms can reach higher altitudes. Also, O_2 is photo-dissociated into free oxygen atoms. Figure 2 shows the composition of various atoms, molecules, and ions vs height for the midlatitude ionosphere/thermosphere. We see in this figure that oxygen becomes dominant at 200 km and hydrogen above 700 km. Similarly, the ionosphere is primarily made up of H^+ (with some He^+) at very high altitude, O^+ in the height range near the peak density, and a mixture of O_2^+ and N_2^+ and NO^+ in the lower thermosphere. Hydrogen is so light that it can escape the earth's gravity and form the earth's geocorona, a halo of hydrogen analogous to the sun's glowing corona seen during an eclipse. By chance, hydrogen and oxygen have almost identical ionization potentials, so charge exchange is a very easy process:

Figure 1 Typical profiles of neutral atmospheric temperature (a) and ionospheric plasma density (b) with the various layers designated. that is, if O^+ is surrounded by H gas, after a while an oxygen ion will give up its charge to form a hydrogen ion (H^+). This explains why O^+ ions formed at low altitudes during daytime become H^+ ions at very high altitudes.

Gravity and pressure are not the only forces with which the ionosphere must deal. The earth's dipole magnetic field lines force the hydrogen ions to travel on closed trajectories between the hemispheres since following the magnetic lines is easy, but moving across them is not. The particle motion is like a helix, moving in circles around the magnetic field lines while freely moving parallel or antiparallel to the direction of the field lines. This motion results in the entire region (in a toruslike shape shown in Figure 3) filling with a hydrogen plasma during the daytime (whose source is the sunlight ionization of oxygen coupled with charge exchange). During the night, this region, called the plasmasphere, starts to unload downward into the ionosphere by the reverse process, tending to maintain the oxygen plasma in the ionosphere during the night with the whole process starting over the next day. Why the plasmasphere abruptly ends at about 4 earth radii (60° magnetic latitude) is very interesting and is discussed below.

Refilling from above is not the entire reason for the ionosphere lasting all night, however. It turns out that charged atoms cannot easily recombine with an electron, since in a reaction such as

it is very difficult to simultaneously conserve energy and momentum, and the reaction rate is very small. But in the following reactions

Figure 3 A toroidal region of high plasma density exists around the Earth on average within the region shown. These magnetic flux tubes are filled with plasma of ionospheric origin during the day and discharge only slowly at night.

there are two end products, and this difficulty does not arise. Reactions [5a,b] are called dissociative recombination and are very fast. This explains why the molecular ions (seen in Figure 2) at low altitudes disappear at night, leaving the O^+ plasma above as the distinct nighttime layer (shown in Figure 1). In fact, reaction [4] is so slow that O^+ is actually lost through a two-step process such as, for example, charge exchange followed by [5a]

or ion-atom interchange followed by [5b]

Both [5a] and [5b] leave oxygen in an excited state, which emits both red (630 nm) and green (557.9 nm) light that is visible from the ground to sensitive cameras. Such emissions are called airglow and give us a tool for visualizing the ionosphere, as shown in the next section.

To summarize what we have learned thus far, the ionosphere is created during the daytime by X-rays and EUV from the sun that are absorbed while heating and ionizing the outer layer of the atmosphere. This action heats the gas to temperatures over 1000 K, explaining why it is called the thermosphere. The plasma, which is primarily O^+ above 200 km, diffuses upward against gravity, reaching so high that charge exchange with the geocorona converts the ionosphere to a H^+ plasma, which can escape gravity. But it is constrained by the dipole magnetic field to a toruslike configuration, filled during the day and emptied at night. In the lower thermosphere, molecular ions dominate, but they disappear quickly after sunset, leaving a slowly decaying O^+ layer.

A Day in the Life of the Midlatitude Ionosphere

The most powerful single tool for ionospheric studies is an incoherent scatter radar that detects the microscopic fluctuation due to thermal motions in the ionosphere. The first such

instrument, and still the largest of the eleven now in use worldwide, is near Arecibo, Puerto Rico. The dish is 1 km in circumference and can ‘see’ the ionosphere out to several 1000 km altitude. In [Figure 4](#), we show the plasma content measured by the radar over a full day. The discussion in the [Section Sources and Fundamental Features of the Ionosphere](#) explains the basic character of this plot, but not at all its details. We see that the density is high during the day, even at 100 km. At night the lower ionosphere rapidly – and almost completely – disappears, so much so that to see anything at all we must change the altitude and gray scale. Then slowly during the night, the density decays to low values just before sunrise, when the cycle begins again. But what about the wiggles? Why does the layer move up and down? And what is the origin of the weak ionization layers seen at low altitudes?

These effects in large part are due to horizontal winds and waves in the thermosphere. With a very hot atmosphere on the dayside (>1000 K) in full sunlight and a very cool one at night (<800 K), it is not surprising that strong winds blow from day to night continuously all over the globe. Unlike the thick lower atmosphere, the thermosphere has no thermal inertia. The winds simply blow continuously, acting as a huge atmospheric thermal tide. Speeds of 200 m s^{-1} (720 km h^{-1}) are not uncommon. It is very hard to move the plasma across the magnetic field lines, but such winds easily move the ionosphere up and down the magnetic field lines. At Arecibo, the direction of the magnetic field is at an angle of 45° to the

vertical (pointing northward and downward). When the wind blows southward, the ionosphere moves upward, much like a ping-pong ball held up against gravity on an inclined plane by a hair dryer, as shown in [Figure 5](#).

At high altitude there is very little neutral gas, and recombination is weak. If the wind ceases or blows north, the ionosphere falls due to gravity into regions where [reaction \[5a,b\]](#) can eat away at it. So a southward wind not only elevates the ionosphere, it also keeps it high out of reach of the losses due to the thermosphere. Some of what we see at night in [Figure 4](#) is due to these winds.

The more abrupt changes in height may be due to the electrical forces that act on the ionosphere. These electric fields have associated voltages as high as 200 000 V and ionospheric currents as great as 1 000 000 A, yielding power levels of 2×10^{11} Watts, more power than any artificial generator on earth. Two major generators provide this electrification and both involve motion of a conductor across a magnetic field, exactly the manner by which generators convert mechanically rotating machines into electric energy. The solar wind is the most powerful of the two, generating hundreds of kilovolts across the earth’s polar regions and causing one of nature’s most spectacular visual displays – the aurora borealis and australis (see the next section). The second generator is the motion of the earth’s atmosphere, described in previous paragraphs. Tides, winds, and gravity waves in the atmosphere all drive currents and generate electric fields by the dynamo effect.

Figure 4 Ionospheric plasma density over Arecibo during a 24-h period (16–17 September 1999; time is Atlantic Standard Time). The lack of plasma below 250 km at night is due to recombination of molecular ions. The high-altitude plasma and interesting thin layers are due to ions such as O⁺, Mg⁺, and Fe⁺, which have long lifetimes.

Figure 5 An illustration showing the analogy between the midlatitude ionosphere on the right, with atmospheric winds pushing the ionosphere up the magnetic field, and a light object suspended on an inclined plane.

Because the magnetic field lines behave like conducting wires, the only voltage easily allowed is across magnetic field lines. **Figure 6** illustrates what happens if a single positive particle is subjected to orthogonal electric and magnetic fields. Initially, the particle is accelerated parallel to the electric field by the force qE .

But once it attains a velocity, the magnetic force, $q\mathbf{V} \times \mathbf{B}$, deflects it to the right. Eventually, it comes to rest and the cycle starts over. The pattern is the same as a dot on the edge of a rolling, nonslipping wheel moving to the right at a velocity E/B . A negatively charged particle (electron) starts out in the opposite direction, but is also deflected to the right, and drifts on average at the same speed as the positive ions. Since there are equal numbers of positive ions and electrons, there is no net current – just a net velocity. Above about 150 km, collisions are so rare that **Figure 6** describes the motion quite well – electric fields are one-to-one, related to the motion of the ionosphere across the magnetic field lines, whereas winds, gravity, and diffusion dominate along the direction of the magnetic field. An eastward electric field over Arecibo, for example, causes an $(\mathbf{E} \times \mathbf{B})B^{-2}$ drift northward and upward at an angle of 45° . Some of the abrupt height changes visible in **Figure 4** are due to such electric field–induced motions.

The abrupt height changes might be temporal or spatial or a combination of both; it is difficult to tell with a single measurement. But the fact that red light is emitted in [reactions \[5a\] and \[5b\]](#) allows us to visualize the plasma in two dimensions. The data in **Figure 7** were obtained on this same night using a bare, backlit charge-coupled device chip

illuminated by a fisheye (all-sky) lens. A narrow (630 ± 1 nm) filter was inserted in the path and the chip was exposed for 90 s. There were 1024×1024 pixels in the image, which, at a height of 250 km, covers a 1000-km diameter circle. The image has been corrected for the lens effects, vignetting, etc., and projected as if we were above the earth looking down rather than up (hence the map of the Caribbean in its usual geometry). We see intricate patterns of light and dark regions, with one of the dark zones positioned right over the Arecibo Observatory. The ionosphere is highly structured this night and is far different than would be predicted if only production, loss, gravity, and diffusion were operating. The sequence of images taken this night shows the dark bands surging poleward from well south of Puerto Rico and then drifting toward the west. This unexpected behavior demonstrates that we have much to learn about even the most well-behaved regions of the ionosphere.

Fire and Ice: The High Latitude Ionosphere

Other entries in the *Encyclopedia of Atmospheric Science* discuss the aurora and the earth's magnetosphere at some length. Here we discuss some of the more striking features of the ionosphere in this region. First of all, the light emissions we call the aurora also are due to the impact of energetic particles on the atmosphere, primarily electrons. Some of these particles leak in from the solar wind, but most are accelerated from the background plasma at a height near 5000 km above the earth. The earth has

Figure 6 In crossed electric and magnetic fields in vacuum, ions and electrons exhibit the motion shown schematically. The ion path is specifically shown to be similar to that of a dot on the rim of a rolling wheel.

Figure 7 The 630 nm airglow for 17–18 February 1999, superimposed on a map of the Caribbean islands with Puerto Rico in the center. The regions depleted of airglow (shown black) commenced in the SE and surged to the NW on this night. Caribbean Ionosphere Campaign, year one: airglow and plasma observations during two intense midlatitude spread-F events. *Geophysical Research Letters* 27, 2825.

Figure 8 A spectacular view of the eastern half of the United States during a major auroral display.

its own ‘cosmic ray’ generator, just as do pulsars, Jupiter, and other magnetized objects in the cosmos. **Figure 8** shows a view of the earth from 800 km during a spectacular aurora. Close inspection of the city lights shows that the aurora reached Madison, Wisconsin and covered most of the Great Lakes region.

Since intense light must be accompanied by the production of plasma, the aurora is a highly dynamic source of the ionosphere wherever and whenever it appears. **Figure 9** gives some insight into its global character. The view is from 5000 km and shows rings of light circling the top (and bottom) of the earth’s polar regions like a halo. This auroral oval waxes and wanes in size, sometimes (as seen in **Figure 8**) reaching highly populated regions, but usually limited to the mid-Arctic zone.

During certain conditions in the solar wind (when the interplanetary magnetic field is parallel to the earth’s magnetic dipole), the solar wind electric field is transmitted very efficiently along the earth’s magnetic field and throughout both polar ionospheres. At these times, a magnetic storm often occurs and great aurora results. Since the earth’s magnetic field is nearly vertical near the pole, the $(\mathbf{E} \times \mathbf{B})B^{-2}$ drifts are nearly horizontal. Thus, two huge circulation cells often occur in the ionosphere. If the magnetic storm continues for more than an hour or so, the neutral atmosphere can also be put into

Figure 9 The sequence begins at 05:29 UT on 2 April 1982 (upper left image) as the NASA/GSFC spacecraft Dynamics Explorer 1 first views the auroral oval from the late evening side of the dark hemisphere at low northern latitudes near apogee (3.65 Earth radii altitude) and then from progressively greater latitudes as the spacecraft proceeds inbound over the auroral oval toward perigee. The poleward bulge at onset of the auroral substorm is observed beginning at 06:05 UT (fourth frame). In successive 12-min images, the substorm is observed to expand rapidly in latitude and longitude. Photograph courtesy of Frank, L.A., Craven, J.D., Rairden, R.L. University of Iowa. motion. Remarkably, the coupled solar wind and ionosphere actually put the earth’s atmosphere in motion. Heat is also generated by the electric currents, which change the global circulation.

The polar circulation rips away at the plasmasphere, reducing its size and compressing it to lower latitudes. After the storm and over a few days, the region refills with cool dense plasma out to about 4 earth radii and 60° magnetic latitude. This altitude/latitude region is where the solar wind and earthly wind dynamos have approximately equal control of the ionosphere/plasmasphere/magnetosphere system. During a great magnetic storm, the composition of the thermosphere can be seriously modified, even worldwide, creating great negative ionospheric storms wherein the ionosphere virtually disappears for a day, even in full sunlight. The atmosphere changes so much that the earth acts like some other planet, one with very little oxygen, in fact. The solar cycle maximum of 2001 promises many exciting scientific discoveries as we continue to instrument the earth and its surrounding near space regions. We also expect that space weather will become more relevant to mankind, as discussed next.

Space Weather

There are many aspects of space weather that are relevant to human habitation, particularly as we become more dependent on technology- and space-based systems. Some of these aspects involve the ionosphere and are described here. Others are related to magnetospheric phenomena, such as the killer electrons of the radiation belt, which create havoc in satellite systems, and solar proton events, which create severe radiation levels for astronauts building the space station.

Rapidly changing magnetic fields due to the vast ionospheric currents flowing in a major auroral event create electrical voltages at the surface of the earth, just as they do in an electrical transformer. Vast power grids are the perfect detector of these voltages, which are unexpected and thus can trigger the unnecessary shutdown of elements along a grid. During the great storm of the last solar cycle, the Province of Quebec went dark for 12 h because of such a surge. Today, our power grids are even more interconnected, and predictions of such conditions are becoming both of more practical importance and of some practical feasibility. Such predictions are among the first challenges of the fledgling National Space Weather Program in the United States as well as the global counterpart of this new program.

Some important space weather effects are strictly due to the earth's dynamic atmosphere without help from the solar wind. The midlatitude weather discussed earlier is of this type and is fairly rare. But near the magnetic equator (where the magnetic field lines are exactly horizontal), severe convective storms occur night after night in some seasons and longitudes. The ionosphere is so dense at the equator that such storms create havoc with communication systems

using radio waves, which must propagate through the ionosphere from satellites to the ground. In brief, in such storms the satellite signals 'twinkle,' just as starlight does passing through the turbulent lower atmosphere. This creates deep fades and distortions in satellite signals, which disrupt communications. The higher the radio wave frequency, the less ionospheric turbulence creates problems. However, even at the high frequencies of the Global Positioning System (GPS) satellites (>1 Gigahertz), ionospheric effects can occur.

Figure 10 is a space weather radar map obtained over the magnetic equator near Lima, Peru. The dark areas reveal where ionospheric turbulence exists. On this night, severe weather erupted just after sunset and lasted for several hours, its effects extending to over 1000 km altitude. Radio signals propagating through this region would be seriously degraded.

The Ionosphere as an Earthquake Predictor

Heki (2011) showed that for large earthquakes ($M > 8$), the total electron content (TEC) between GPS satellites and the ground appears to change by 10%.

However, more likely the ionosphere simply changes altitude, which in the TEC can appear to be a rise or fall. Kelley et al. (2012) explained this phenomenon as due to precursor electromagnetic waves detected prior to earthquakes (Fraser-Smith et al., 1990). The electric field in such waves will cause the ionosphere to rise or fall according to the work by Beach et al. (1997). This idea could be incredibly important, both for saving lives and economically.

Summary

We have learned much about the ionosphere since its discovery near the beginning of the twentieth century, when Marconi first skipped radio waves off it all the way across the Atlantic. The Space Age rocket and satellite probes, along with powerful ground-based radars, have revealed much about its properties. New things are still being discovered, but we are also entering an age of prediction. The goal of the US National Space Weather Program is predicting the onset of severe space weather, much as the meteorology community predicts severe storms in the lower atmosphere. However, the scale of the interacting system stretches from the sun to the earth and is much more variable than the solar constant that directly heats the earth's lower atmosphere. In addition, this vast region of space has few observing stations, and the challenges of predicting its behavior are enormous. Remarkably, the ionosphere also seems to be an enormous detector of earthquakes before they happen.

Metal Layers

JMC Plane, University of Leeds, Leeds, UK

Synopsis

The ablation of interplanetary dust particles is the source of the metal atoms – Na, Fe, Mg, K, and Ca – that occur in layers between 80 and 100 km. The relative abundances of these metal atoms are quite different from their relative abundances in chondritic meteorites, mostly because elements ablate with widely different efficiencies. Sporadic E layers are concentrated layers of metallic ions and electrons that occur above 90 km and have an important influence on radio communications. Meteoric smoke particles, formed by the condensation of metallic compounds, are the major source of nuclei for noctilucent clouds.

Introduction

The ablation of interplanetary dust particles generates a daily input of about 20 tonnes of a variety of metals into the Earth's upper atmosphere. This gives rise to the layers of neutral metal atoms that occur globally at altitudes between 80 and 100 km. Several of these metals (sodium, iron, potassium, calcium, and lithium) possess suitable optical transitions and can be observed from the ground by the spectroscopic techniques of photometry and lidar. These metals occur as free atoms because above 80 km the concentration of atomic oxygen (O) exceeds that of ozone (O₃): while O₃ oxidizes metal atoms to metal oxides that then go on to form a variety of compounds such as hydroxides, carbonates, and bicarbonates, atomic oxygen and associated atomic hydrogen reduce these compounds back to metal atoms. Above 100 km the metals become ionized by charge transfer with the increasing levels of E region ions such as NO⁺ and O₂⁺.

Surprisingly, the relative abundances of the metal atoms are quite different from their relative abundances in chondritic meteorites. For example, atomic calcium is depleted by more than two orders of magnitude with respect to sodium. The metals also exhibit different seasonal behavior: the integrated column densities of all the metals peak in early winter, but sodium and iron have a marked midsummer minimum, whereas calcium and potassium have a secondary midsummer maximum and hence little seasonal variation. The explanation for these differences appears to be a combination of differential ablation (e.g., the least volatile metal, calcium, is ablated about 10 km lower in the atmosphere than sodium), and differences in the gas-phase chemistries controlling the layers.

Sporadic metal layers are observed between about 95 and 120 km. These are short-lived thin layers of neutral metal atoms that appear explosively on top of the background layers. They are most probably linked to sporadic E layers, which are concentrated layers of metallic ions and electrons that occur between 90 and 130 km and that have an important influence on radio communications.

Lidar enables the metallic layers to be observed with excellent spatial and temporal resolution. Hence, the metal atoms can be used as tracers of dynamical processes such as gravity waves and tides. Narrow-linewidth lidar observations of

the hyperfine structure of the Na- and K-D-lines have also been used to measure temperature and wind speed with excellent precision. Temperature profiles can also be obtained with a technique which uses a two-color lidar to observe the relative populations of the lowest spin-orbit states of atomic iron.

Finally, meteoric metals affect the atmosphere in a number of ways. Sporadic E layers have a significant effect on the electrical conductivity of the lower thermosphere. In the mesosphere, metallic compounds in the form of individual molecules or dust particles appear to be the major source of nuclei for noctilucent cloud formation. In the stratosphere, metal-rich dust may influence ozone chemistry, by providing condensation nuclei for sulfate particles in the Junge layer and affecting the freezing point of polar stratospheric clouds. In the troposphere, the deposition of soluble meteoric iron into the Southern Ocean may represent a significant fraction of bioavailable iron, which would have important climate feedbacks.

Meteoric Ablation as a Source of Mesospheric Metals

The magnitude of the input of interplanetary dust particles into the Earth's atmosphere is actually rather uncertain. Even recent estimates of the dust input vary from 5 to 270 tonnes per day. The input rate is so uncertain because no single technique can observe particles over the mass range from about 10⁻¹² to 1 g, which makes up the bulk of the incoming material. Furthermore, the interpretation of observations within the atmosphere, as well as deposits in ice cores and deep-sea sediments, are affected by uncertain atmospheric transport and deposition patterns. Most of the dust in the inner solar system comes from Jupiter family comets (perhaps as much as 90%). These are comets with short orbital periods of a few decades, and an aphelion close to the orbit of Jupiter. The remaining dust comes from the asteroid belt between Mars and Jupiter; and Halley family and Oort cloud comets, which have orbital periods of centuries. Dust particles from long-decayed cometary trails and the asteroid belt give rise to a continuous input of sporadic meteoroids into the earth's atmosphere. In addition, the dust-rich trails from comets, which recently crossed the earth's orbit (i.e., within the past century or so), are the source of meteor showers (e.g., the *Perseids* and *Leonids*), although

these provide a much smaller mass flux on average than the sporadic background. Dust particles drift into the inner solar system because the pressure of solar photons causes the orbital velocities of particles with a radius larger than about $1\text{ }\mu\text{m}$ to decelerate – a process known as Poynting–Robertson drag. Most of the dust mass should be contained in particles with masses in the range $1\text{--}10\text{ }\mu\text{g}$ (radius $50\text{--}150\text{ }\mu\text{m}$), which enter the terrestrial atmosphere from a near-prograde orbit with a mean speed around 14 km s^{-1} .

Interplanetary dust particles enter the atmosphere at speeds between 11 and 72 km s^{-1} if they originate within the solar system. High energy inelastic collisions with air molecules lead to sputtering of elements from the particle surface. Most particles with masses in excess of $1\text{ }\mu\text{g}$ also rapidly heat up until they reach a melting point around 1850 K . Evaporation of atoms and oxides from the molten particle – a process termed meteoric ablation – is then very rapid, usually leading to complete evaporation of the particle. The peak ablation altitude is around 90 km . However, for an individual dust particle entering the atmosphere, different elements tend to evaporate at different altitudes, a process termed differential ablation, i.e., the most volatile elements – Na and K – ablate first, followed by the main constituents Fe, Mg, and Si, and finally the most refractory elements such as Ca, Al, and Ti. The major metallic constituents of meteorites by elemental abundance are Mg 14.4% , Si 13.6% , Fe 12.1% , Al 1.2% , Ca 0.82% , Na 0.80% , Ni 0.67% , K 0.05% , and Ti 0.03% .

Techniques for Observing Metals in the Mesosphere

The first quantitative observations of metal atoms were made in the 1950s using ground-based photometers that measured the resonance fluorescence from spectroscopic transitions of the metal atoms excited by solar radiation. Emission lines from Na, K, Fe, and Ca^+ were successfully observed because these metals have extremely large resonant scattering cross sections. A large scattering cross section is essential because their concentrations relative to the general atmosphere are less than 100 parts per trillion (100×10^{-12}). Photometers are generally pointed to near zenith during twilight, when the geometrical shadow height of the Earth (the terminator) is close to mesospheric altitudes. Radiative transfer theory is used to derive the vertical concentration profile from the variation of the emission signal as the terminator passes up through the metal layer.

Photometry was superseded in the 1970s when the discovery of tunable laser sources allowed the development of the resonance lidar (laser radar) technique. In this technique, a pulsed laser beam is tuned to a strongly allowed spectroscopic transition of the metal atom of interest, and transmitted up through the atmosphere. The laser pulse is Mie- and Rayleigh-scattered, particularly in the lower atmosphere where there are aerosol layers and the pressure is greater. In the mesosphere, the pulse is resonantly scattered by the metal atoms. A small fraction of the scattered light returns to the ground, where it is collected by a telescope and measured by photon-counting. The return signal is electronically binned to provide the range and hence height resolution of the scattering layer, typically to within 40 m . The absolute metal density is calibrated from the Rayleigh-scattered cross section at a lower altitude of known

atmospheric temperature and density. Lidar has so far been used to observe Na, K, Li, Ca, Ca^+ , and Fe.

The technique has a number of important advantages over photometry. The first is that observations can be made continuously over a complete diurnal cycle, provided an astronomical-quality telescope and narrowband optical filter are employed for daytime measurements. The second is that observations can be made rapidly (typically every 60 s for the Na layer), so that the metal layers can act as tracers of atmospheric motions such as tides and gravity waves. Third, in the case of Na and K, a narrow-linewidth laser can be used in the lidar transmitter to measure temperature and wind profiles in the upper mesosphere. This is possible because the absorption spectrum of each D-line contains hyperfine structure. For example, the D_2 absorption spectrum consists of six hyperfine resonance lines, which become blended at temperatures above 6 K . The degree of blending is very sensitive to temperature, so, employing a laser with a tuning accuracy and frequency stability of at least 50 MHz to scan across the D_2 absorption spectrum, the temperature can be measured with an uncertainty $\approx 1\text{ K}$. The laser can also be scanned to the wings of the D_2 absorption peak in order to measure the Doppler width of the peak. From this the radial wind (i.e., along the line-of-sight of the lidar) can be calculated with an error of less than 3 m s^{-1} , and can then be resolved into the vertical and zonal wind components. A recent development has been to use a two-laser lidar operating at 372 and 374 nm to measure the relative populations of the spin-orbit multiplets of ground state $\text{Fe}(^5\text{D})$, which are related to temperature through the Boltzmann equilibrium.

There have also been a number of measurements by rocket-borne mass spectrometers of the concentrations of positive metallic ions in the upper atmosphere. These flights have been motivated by an attempt to establish a link between meteor showers and the abundance of metallic ions, and to study the role of metallic ions in forming sporadic E layers (see below). Metallic ions such as Mg^+ have also been observed by resonant scattering of sunlight, using spectrometers on satellites and the space shuttle. Satellite observations have also provided the first global picture of the neutral Na and Mg layers.

Observations of Metallic Species in the Atmosphere

Figure 1 shows profiles of the annual mean layers of Na, Fe, K, and Ca observed by lidar at several midlatitude locations. Note that although magnesium is the most abundant meteoric metal, atomic magnesium cannot be observed from the ground because its optical transition at 285.2 nm is obscured by the stratospheric ozone layer. The Na layer has been studied in greater detail than those of the other metals because it is the easiest metal to observe spectroscopically. The column density of Na is about $5 \times 10^9\text{ atoms cm}^{-2}$, although this can vary by a factor of 10 depending on time and location. The layer exhibits a seasonal variation with a wintertime maximum, which is also latitude dependent. For instance, at low latitudes the winter enhancement is only about 1.3:1, whereas at midlatitudes this variation increases to about 3:1 and to more than 10:1 in the polar regions. The height of the peak of the Na layer varies between 88 and 92 km , with the

Figure 1 Vertical profiles of the annual mean concentrations of Fe, Na, K, and Ca measured by lidar at a number of midlatitude locations in the United States and Europe.

highest peak heights occurring during summer. The full width at half-maximum (FWHM) of the layer is about 10 km, and it is usually characterized by strikingly small scale-heights of 2–3 km on the top and bottom sides of the layer (the scale height is the distance over which the concentration changes by a factor of e (2.718...)).

The other neutral metal layers that have been observed in the upper atmosphere are those of Fe, K, Ca, and Li. **Figure 2** illustrates the relative column abundances of these metals to that of Na, plotted against their relative abundances in chondritic meteorites recovered from the Earth's surface. Since there is strong evidence that meteoric ablation is the major source of the metals, a good correlation might be expected. Apart from lithium for which there is a rather small observational database, the other metals are all depleted with respect to sodium. In particular, calcium is depleted by the enormous factor of 120–360 depending on season. There are other unexpected differences in the layers. Compared with the peak of the sodium layer, the lithium peak is about 4 km higher, while the potassium, calcium, and iron peaks are several kilometers lower and have considerably smaller scale-heights, as shown in **Figure 1**.

Figure 2 Relative annual average abundances of meteoric metal atoms (at midlatitudes), compared to their relative chondritic abundances.

Lidar observations have also revealed the curious phenomenon of sporadic metal layers. These are very thin, concentrated layers of neutral metal atoms that occur at altitudes between 90 and 110 km, sometimes appearing within a matter of minutes and then surviving for perhaps a few hours. The average FWHM of these sporadic layers is only about 2 km, and their peak concentrations can be as much as 40 times the peak of the background metal layer. They have also been observed with a horizontal extent of more than 1000 km. In explaining this intriguing phenomenon, it has been noted that sporadic layers commonly occur together with sporadic E layers. These are thin layers of metallic ions that can be formed by horizontal wind transport across magnetic field lines, which produces convergence of the ions into layers at null points in the wind shear. Sporadic neutral layers can then result from metal ions forming ion clusters that undergo dissociative recombination with electrons (see below). However, there may well be other mechanisms for sporadic layer formation, including auroral precipitation acting on meteoric dust particles.

Metallic Species in the Earth's Airglow

It was first reported in 1929 that radiation at 589 nm is present in the nightglow spectrum. A decade later it had been established that this radiation is due to the transition $\text{Na}(3^2\text{P}_{3/2,1/2} - 3^2\text{S}_{1/2})$ from a source located within the Earth's atmosphere. Sydney Chapman then postulated the sequence of [reactions \[I\] and \[II\]](#) to account for the emission.

Historically, there have been two significant problems associated with validating the Chapman mechanism. The first was that the rate coefficients for [reactions \[I\] and \[II\]](#) have to be fast enough to generate the measured D-line emission intensity of 50–200 R (1 Rayleigh = 10^6 photons $\text{cm}^{-2} \text{s}^{-1}$ emitted in all directions). However, laboratory measurements (see below) have now confirmed that both reactions are extremely fast. [Reaction \[I\]](#), which is rate determining, proceeds via the electron jump (or harpoon) mechanism. The second problem was the size of the branching ratio, f , for production of $\text{Na}(^2\text{P})$ in [reaction \[II\]](#). Geophysical models of the Na layer show that f has to be ~ 0.1 , in agreement with a field experiment in which a rocket carrying a sodium photometer was launched through the Na layer while a ground-based lidar observed the sodium atom concentration.

A series of elegant laboratory experiments have shown that [reaction \[I\]](#) produces NaO almost entirely in the low-lying $\text{NaO}(\text{A}^2\Sigma^+)$ excited electronic state, rather than the $\text{NaO}(\text{X}^2\Pi)$ ground state. The $\text{NaO}(\text{A})$ state has a long radiative lifetime and is not quenched efficiently, so that in the mesosphere [reaction \[II\]](#) involves both $\text{NaO}(\text{A})$ and $\text{NaO}(\text{X})$ reacting with O. Another lab experiment has shown that f for $\text{NaO}(\text{A}) + \text{O}$ is 0.14 ± 0.04 , thereby reconciling the geophysical observations with the underlying chemical physics.

A further twist to the Na D emission is that the ratio of the two lines at 589.0 and 589.6 nm, which comprise the doublet is not constant (uniquely among the various atomic and

molecular emissions in the earth's nightglow). The average ratio is about 1.67, but this can vary by $\pm 20\%$. This variation appears to be due to a competition between the reaction $\text{NaO(A)} + \text{O}$, which should generate $\text{Na}(^2\text{P}_j)$ with a $J = 3/2$ to $1/2$ propensity of 2.0, or quenching of NaO(A) to NaO(X) by O_2 . The resulting NaO(X) then reacts with O to generate $\text{Na}(^2\text{P}_j)$ with a $J = 3/2$ to $1/2$ propensity of 1.5, where these propensities are derived from theoretical statistical correlation arguments. The D-line ratio should therefore vary between 1.5 and 2.0, depending on the local ratio of O to O_2 .

Modeling of Metallic Layers

Since the only metal species that can be observed directly in the mesosphere are the atomic neutrals and ions, our understanding of the chemistry that forms the metal layers has come from a combination of laboratory studies and modeling. Up until the 1980s, laboratory measurements of the rate coefficients for reactions involving metallic species were available only for ion-molecule reactions, which were studied in ion drift tubes. However, since then the two classical techniques of flash photolysis and the fast flow tube have been applied with great success to the challenging task of studying reactions of neutral metallic species in the gas phase at the low temperatures characteristic of the upper atmosphere. In addition, photoelectron spectroscopy and molecular beams have been employed to investigate the production of excited states in exothermic reactions. While most laboratory work has concentrated on sodium chemistry, there is now a growing database on reactions of iron, magnesium, calcium, and potassium.

Figure 3 is a schematic diagram of the gas-phase chemistry of sodium that is employed in current models. Almost all of

Figure 3 The significant chemical cycles of sodium in the upper mesosphere/lower thermosphere region. Major sodium species are shown in the gray boxes. Thin solid black lines indicate reactions with measured rate coefficients. The broken lines are measured photodissociation reactions. The gray solid lines are dissociative electron recombination reactions, which have not yet been studied.

these reactions have now been studied in isolation under conditions appropriate to the upper mesosphere. Figure 4 illustrates vertical profiles of the major sodium compounds, predicted from a one-dimensional model incorporating the chemistry in Figure 3. Above the atomic sodium layer at around 90 km, ion chemistry predominates. Sodium atoms are ionized mostly by charge transfer with the ambient NO^+ and O_2^+ ions, with a small contribution from solar photoionization. Dielectric recombination (i.e., $\text{Na}^+ + \text{electron} \rightarrow \text{Na}$) is a very inefficient process. Instead, Na^+ is neutralized by forming clusters, which then undergo dissociative recombination with an electron. The rate of neutralization is governed by the initial formation of $\text{Na} \cdot \text{N}_2^+$, followed by a competition between atomic O and CO_2 , the former converting the cluster back to Na^+ , and the latter forming a stable cluster that will subsequently react with an electron.

Below 90 km, Na becomes converted to the stable reservoir NaHCO_3 , via a series of steps beginning with the oxidation of Na by O_3 to NaO . As shown in Figure 3, species such as NaO , NaOH , and NaHCO_3 are converted back to Na by reaction with O and H . The rates of the reaction between atomic hydrogen and NaHCO_3 , as well as its photodissociation, have been shown in the laboratory to be slow, so that NaHCO_3 should be the major reservoir below 84 km, as shown in Figure 4. NaHCO_3 is assumed to then polymerize with other metallic compounds to form meteoric smoke (see below), hence its predicted decrease below 80 km. Note, however, that there have not yet been direct observations of NaHCO_3 in the atmosphere. It is only when O and H become abundant above 85 km that atomic sodium becomes the dominant form. Hence, the small scale-height on the underside of the Na layer mirrors the fall-off in atomic O and H .

The chemistries of iron, magnesium, and calcium are somewhat different from that of sodium. Unlike Na^+ , the ions Fe^+ , Mg^+ , and Ca^+ are chemically active, reacting with O_3 to form oxides and forming strongly bound dioxides with O_2 . The rate of neutralization of these metal ions is governed by competition between atomic oxygen and electrons for the metal oxide ions. The removal of metal atoms on the underside of the layer involves oxidation by O_3 to form neutral metal oxides, followed by recombination with O_2 , CO_2 , or H_2O to form the trioxide, carbonate, or dihydroxide, respectively.

Figure 4 Diurnally averaged height profiles of Na , Na^+ , and NaHCO_3 , predicted by a one-dimensional model for January, 40°N .

Although the dihydroxide (e.g., $\text{Mg}(\text{OH})_2$) is thermodynamically most stable, it is not formed very rapidly because of the dryness of the upper mesosphere. Hence, it is not clear at present which of these compounds form the major reservoir species for these three metals.

Models using the sodium chemistry in Figure 3 are able to reproduce very satisfactorily the observed Na layer as a function of season and latitude. Models for the Mg, Fe, K, and Ca layers have also been published recently. As Figure 1 shows, although there are differences in the heights and shapes of these layers with respect to the Na layer, these differences are of second order. This implies that the enormous deviations in the metal abundances from their expected chondritic ratios (Figure 2) are not primarily due to differences in chemistry, but are due to differential meteoric ablation. Indeed, current models require iron and calcium ablation efficiencies of about 25 and 5%, respectively. Models of iron and calcium are able to explain quite satisfactorily most of the seasonal differences between these metals and sodium. However, the very surprising differences between sodium and potassium, which are from the same group in the Periodic Table, remain to be fully explained.

The formation of sporadic metal layers has also been successfully modeled using ion-molecule chemistry of the kind illustrated for Na^+ in Figure 3. Sporadic E layers tend to descend between 120 and 95 km under the influence of the diurnal tide, at a rate of a few km h^{-1} . O_3 and the general atmospheric density increases with descending height, so that molecular metallic ions (e.g., FeO^+) form more quickly. At the same time, the atomic O density falls, so the reactions involving O which convert metallic oxides back to the atomic ion (e.g., $\text{FeO}^+ + \text{O} \rightarrow \text{Fe}^+ + \text{O}_2$) get slower. Hence, these oxides tend to undergo dissociative recombination with electrons (e.g., $\text{FeO}^+ + e^- \rightarrow \text{Fe} + \text{O}$), generating a layer of neutral atoms.

Models have also been modified to explore perturbations to the metal layers induced by gravity waves. Gravity waves in this region can cause temperature variations of over 20 K and vertical displacements of several kilometers in less than an hour. The motivation for studying the coupling of metal chemistry and dynamics has been to examine whether the metals are suitable inert tracers of atmospheric motion, or whether the apparent dynamical perturbation is amplified by a fast chemical response to changes in temperature and the concentrations of minor species such as O_3 , O, and H. Several studies now show that the sodium layer is a conservative tracer of short-period gravity waves. In contrast, the underside of the iron layer appears to be controlled by fast chemistry, which may lead to significant chemical amplification.

Impact of Meteoric Metals in the Mesosphere and Stratosphere

In the mesosphere below about 85 km, metallic compounds polymerize together to form aerosols called meteoric smoke particles. Since the major meteoric constituent elements are Fe, Mg, and Si, and these appear to ablate at similar rates and altitudes, it is likely that the smoke consists of amorphous Fe–Mg silicate particles about 1 nm in radius. Smoke particles have been detected by rocket-borne charged particle detectors, since a fraction of them is charged by the uptake of ambient

electrons. Meteoric smoke has also been observed by optical extinction using a spectrometer on the Aeronomy of Ice in the Mesosphere Satellite.

It has been proposed that metallic species play a major role as the source of condensation nuclei for noctilucent clouds (also termed polar mesospheric clouds). These are ice clouds that occur between 82 and 85 km, at high latitudes during summer. They were first observed in 1886 and are increasing in frequency-of-occurrence and brightness, and spreading to lower latitudes. The clouds have therefore been studied intensively as indicators of climate change in the upper atmosphere. The changes in the clouds probably result from increasing water vapor concentrations and decreasing temperatures in the upper mesosphere. Because the upper mesosphere is a very dry region, the condensation nuclei for noctilucent clouds must be particularly effective. Two proposed sources of nuclei are hydrated metallic ions, and meteoric smoke particles, which may be as small as single metal silicate molecules with very large dipole moments. In both cases, strong electrostatic forces promote the binding of water molecules.

Smoke particles are transported within a few weeks to the winter pole, and then descend in the winter polar vortex into the stratosphere. During this period of several months, the particles should grow through coagulation to be around 40 nm in radius. Uptake of sulfuric acid on smoke particles may account for the observed depletion of this acid above 35 km. Laboratory studies show that the particles will then dissolve in the cold, concentrated sulfuric acid droplets that comprise the Junge layer in the lower stratosphere around 20 km. The high concentrations of meteoritic ions such as Fe^{2+} and Mg^{2+} which have been measured in these droplets using airborne aerosol mass spectrometry may affect the freezing point of polar stratospheric clouds, and hence impact on ozone depletion.

Meteoric smoke particles probably enter the troposphere at midlatitudes, where stratosphere–troposphere exchange is driven by atmospheric waves generated by mountain ranges and storm tracks over the North Atlantic, North Pacific, and the Southern Oceans. Within the troposphere, wet deposition (by rain and snow) of these particles appears to dominate over dry deposition. The evidence for this comes from measurements of meteoric smoke in ice cores from Greenland and central Antarctica. A recent study using a general circulation model indicates that there should be a large rate of deposition of meteoric iron into the Southern ocean (50–60° S), where the supply of bioavailable iron to phytoplankton is limited. The resulting Fe fertilization could have important climate feedbacks because phytoplankton draw down CO_2 from the atmosphere.

Polar Summer Mesopause

RH Varney and MC Kelley, Cornell University, Ithaca, NY, USA

Synopsis

The summer polar mesosphere is one of the most fascinating regions of the atmosphere. In full sunlight, the temperature reaches as low as 100 K, far colder than all but a few regions in the solar system. Even though the upper atmosphere is freeze dried, enough water still remains to allow ice crystals to form around meteoric dust particles, leading to the formation of the highest clouds on earth (near 85 km), which form beautiful structures seen in the polar twilight. Interestingly, these clouds were never reported until the end of the nineteenth century and have increased throughout the twentieth century. Many researchers relate this phenomenon to atmospheric change since, as the lower atmosphere heats up, the upper atmosphere cools. In addition, since methane is the main cause of hydrogen in mesospheric water vapor, its increase is a factor in the formation of these clouds. Increased interest in this region was due in part to the huge radar target this region exhibits, 10 000 000 times as large as elsewhere outside of the polar summer. Explanation of these signals has led to a new understanding of the role of dust in a plasma.

Introduction

The mesosphere is the region of the atmosphere located between the stratosphere and the thermosphere, between 50 and 90 km, in which temperature decreases with height. The transition between the mesosphere and the thermosphere is called the mesopause and is the altitude at which the temperature reaches a minimum before increasing with height in the thermosphere. The mesosphere is collocated with the D-region ionosphere, the lowest portion of the partially ionized plasma blanket that surrounds the Earth. The polar summer mesosphere is particularly fascinating. Although the mesosphere has very little water vapor, the highest clouds on Earth are found in this region. Remarkably, in the full polar summer sunlight, the temperature often reaches values as low as 110 K, with one measurement as low as 90 K. This is clearly the coldest natural temperature found on or near the Earth. Additionally, we find an intense radar scattering layer together with atmospheric motions that are dominated by poorly understood gravity waves and tides. These properties are reason enough for scientific interest in the polar mesosphere, but there are important global change aspects as well.

Noctilucent Clouds and the Temperature Anomaly

Interest in the polar summer mesosphere was started on 18 June 1885, 2 years after Krakatoa's eruption in 1883. Silvery-blue clouds were observed from the ground under twilight conditions when the Sun was below the horizon but was still illuminating the mesosphere (i.e., just before dawn or just after sunset). Using photographic triangulation, the height of these clouds was found to be about 82 km, the highest clouds ever seen on Earth. Owing to their unusual nighttime brightness, they were named noctilucent clouds (NLCs). It is believed that a major volcanic eruption introduced a considerable amount of water vapor into the stratosphere that took 2 years to be transported to the mesosphere, eventually contributing to the ice particles that formed these

clouds. The ice particles were large enough to scatter sunlight and be seen by the naked eye. These clouds are only observed during the summer months, usually presenting a wavy pattern, an effect attributed to their interaction with passing gravity waves. The ideal viewing zone is between 53 and 57° latitude because of the long twilight and the polar location of the clouds themselves. The example presented in [Figure 1](#) displays some of the NLC characteristics.

An important discovery was made during the International Geophysical Year of 1957–58. Rocket grenades launched from many locations revealed that, against all expectations, the temperature in the polar summer mesosphere is colder than in the winter polar zone. In fact, a temperature difference of about 100 K exists between summer and winter. More recent data presented in [Figure 2](#) reveal these hemispheric temperature differences quite well, along with the level of temperature fluctuation in the region, which is quite high in the winter hemisphere. This result supports speculations that the NLCs were composed by ice that forms at extremely low

Figure 1 Noctilucent clouds as observed at 2255 UTC on 19 July 1997 from Glengarnork, Ayshire, Scotland. Figure courtesy of Tom McEwan.

Figure 2 Temperature profile measurements taken using radar tracking of falling spheres during summer 1987 (left) and winter 1983–84 (right) over Andoya, Norway. Adapted from von Zahn, U., Meyer, W., 1989. Mesopause temperatures in polar summer. *Journal of Geophysical Research* 94, 1647.

temperatures, even at the low water vapor pressure of the mesopause zone (1–2 ppm).

New ways to study NLCs have been developed that should improve our understanding experimentally. For instance, in the early 1980s, satellite measurements detected NLCs, although, owing to the different method of detection, they were called polar mesospheric clouds (PMCs). They are believed to be the same as NLCs, with the only difference being that, from orbit, they could be observed 24 h a day. In 2007, the Aeronomy of Ice in the Mesosphere (AIM) spacecraft was launched with multiple optical instruments dedicated to studies of PMCs. **Figure 3** shows a composite image of PMCs constructed from multiple orbits of the AIM spacecraft.

Another observation method that is not hampered by lighting conditions takes advantage of the unexpectedly high radar cross section in the polar summer mesosphere. This scattering process is of considerable interest in its own right and is discussed in detail later. The latest way to monitor NLCs involves lidar, a method analogous to radar but using light waves instead of radio waves.

NLCs are usually observed only at high latitudes between 50 and 60°, but on 22 June 1999 they were observed in Boulder, Colorado (40° N), an indication that NLCs are moving south. This phenomenon could be due to cooling and/or increased water vapor caused by rising levels of methane and carbon dioxide due to human activity, a topic discussed later.

Mesospheric Dynamics

The gravity or buoyancy waves that create the interesting structure in **Figure 1** are of more than passing importance in

Figure 3 PMC albedo measured by the Cloud Imaging and Particle Size (CIPS) instrument on the AIM spacecraft. The above image is a composite of 15 orbits on 9 July 2007. understanding the low temperature of the polar summer mesosphere. Such waves are also called internal waves, since they can propagate easily through the atmosphere from one height range to another.

Typical sources include surface wind flow over orographic features, frontal systems, and severe storms; even earthquakes, tsunamis, and nuclear explosions have created substantial waves in the atmosphere. What makes these waves unique and important to the upper atmosphere is that they increase in amplitude as they propagate upward. This seems counterintuitive, but is actually firmly rooted in the principle of energy conservation. The kinetic energy per unit volume in a wave packet is given by eqn [1]:

$$W_{KE} = (1/2)\rho_0(\delta u)^2 \text{ J m}^{-3} \quad [1]$$

In eqn [1], δu is the perturbation wind velocity in the wave (m s^{-1}) and ρ_0 is the background atmospheric mass density (kg m^{-3}). (Since the kinetic energy of a simple molecule of mass M is $(1/2)Mv^2$, measured in joules, exchanging ρ_0 for M yields the kinetic energy density in J m^{-3} .) Similar expressions hold for other forms of energy such as heat and potential energy in a wave packet. The important issue is that, as the wave propagates upward, ρ_0 decreases drastically, exponentially, in fact, with the form for a uniform atmospheric temperature being $\rho_0(z) = \rho_0(0)e^{-z/H}$, where $H = kT/Mg$ is the atmospheric scale height (7 km at surface temperatures) and k is Boltzmann constant. So if energy is to be conserved as a wave propagates upward each time density ρ_0 decreases by a factor of 2, the wave velocity must increase by a factor of $\sqrt{2}$ or about 40%. Eventually, any given wave will reach a height where the amplitude is so great that it breaks. A good rule of thumb is that a wave will break when its internal wave perturbation velocity exceeds its propagation speed. It catches up with itself, steepens, and breaks. Figure 4 shows an analogous situation for water waves. The wave speed slows as the water becomes shallow and, when the internal perturbation velocity exceeds the wave velocity, the wave breaks.

What does this have to do with the cold summer mesopause? When waves break on a beach or in the clear air, they deposit their energy and momentum back into the local medium (swimmers on the surface know this very well). The mesosphere is so tenuous that the input of momentum from waves generated in the dense lower atmosphere is very significant. Current theories of the mesosphere argue that waves reaching these heights come from preferred directions that are different in the two hemispheres. In the summer hemisphere,

Figure 4 Analogy for gravity wave breaking similar to water waves on a beach. After Kelley, M.C., 2009. *The Earth's Ionosphere: Plasma Physics and Electrodynamics*, International Geophysics Series, vol. 96, second (Ed.), Academic Press, Burlington, MA. Reproduced with permission from Elsevier.

the waves preferentially come from the west, depositing a net eastward momentum into the medium. This spins up the atmosphere somewhat and it moves away from the pole. To conserve mass, there is a net upflow at high latitudes, resulting in adiabatic cooling. The opposite effect occurs at the winter pole and the temperature rises.

The preferential direction could arise in a variety of ways, but we discuss only one here: the so-called critical layer effect. Gravity or buoyancy wave velocities are small enough that jet stream winds can be larger than the wave propagation speed. Suppose a wave propagates upward to a height where its horizontal phase speed equals that of the background wind (height h_0 in Figure 5). At this height, the wave is not a wave at all, just some eddies in the flow, and it ceases to exist. In fact, only waves with horizontal velocities greater than u_{max} get through the jet stream at all. But waves propagating in the other direction, against the flow, are never subject to this effect and pass through easily. Since the jet stream is to the west in the summer and to the east in the winter, gravity wave filtering might explain the mechanism described above and the observed temperature asymmetry.

Modern global circulation models can include such effects by parameterizing momentum fluxes. One such model is the Thermosphere–Ionosphere–Mesosphere–Electrodynamics General Circulation Model (TIME-GCM). The calculated yearly variation of temperature at 85 km is shown in Figure 6. We can observe an asymmetry between hemispheres for solstice

Figure 5 Internal gravity waves have phase velocities of the same order as wind speeds in the jet stream. Here we illustrate a wind profile whose peak value exceeds the phase velocity of a particular wave. In this case, an upward propagating wave will reach the critical layer where it is absorbed by the fluid. After Kelley, M.C., 2009. *The Earth's Ionosphere: Plasma Physics and Electrodynamics*, International Geophysics Series, vol. 96, second (Ed.), Academic Press, Burlington, MA. conditions at high latitudes. The southern polar summer hemisphere seems to be warmer than the northern polar summer hemisphere by 100 K.

Polar Mesosphere Summer Echoes

As noted above, an intriguing feature of the polar summer mesosphere is the ability of the region to strongly scatter radio waves. Powerful very high frequency (VHF) (30–300 MHz) radars can detect scattering from turbulent irregularities in the mesosphere at all latitudes and in all seasons. Echoes from the polar summer mesosphere, however, exhibit numerous properties that are unlike echoes from ordinary mesospheric turbulence. Early studies of VHF radar echoes from the high-latitude summer mesosphere and lower thermosphere using the Poker Flat Mesosphere, Stratosphere, and Thermosphere (MST) radar in Alaska (65° N) showed a relatively narrow and surprisingly intense echoing layer centered at about 86 km. The echoes were characterized by their strong VHF (50 MHz) radar backscattering cross section, with backscattered powers 2–3 orders of magnitude greater than typical values observed at low or middle latitudes (in any season) or at high latitudes (in nonsummer periods). The echoes are now referred to as Polar Mesosphere Summer Echoes (PMSEs).

As observed at VHF (~50 MHz), northern hemispheric PMSEs exhibit the following characteristics:

- They display a thin but intense echoing region near the summer mesopause (~85 km) with a margin of ± 3 km.

- While some relatively strong, albeit sporadic, echoes have been reported at latitudes as low as 52°, the strongest, most continuous echoes are observed at latitudes poleward of about 65°.
- The echoes appear around mid-May, last until mid-August, and are relatively continuous.
- Both the height range and seasonal variations of PMSEs correlate reasonably well with those of the cold temperature mesopause (i.e., the coldest known atmospheric region).
- Joint observations using VHF radar and sounding rockets show that intense PMSEs often can be associated with sharp 'biteouts' in the ambient electron density.

Subsequent to their discovery in 1981, many observations related to PMSEs have been made using radar, lidar, and rockets. PMSEs have since been observed using radars at 224, 450, 500, 930, and 1295 MHz, all of which are too high in frequency to ever observe echoes from ordinary mesospheric turbulence. Figure 7 shows an example of simultaneous measurements of PMSEs at three different frequencies. These observations have helped to formulate a number of theories proposed to explain the generation of the intense radar echoes and the remarkable physical conditions associated with them. Subfields in research as disparate as dusty (icy) plasma physics, interplanetary dust cloud studies, meteor ablation, and re-coagulation science all have something in common with the polar summer mesopause region.

Radar scattering from the mesosphere is dominated by scattering from free electrons in the overlapping D-region ionosphere. The scattered radiation from many individual electrons will only be detectable if it adds coherently, which will happen if the structures in the electron density satisfy the Bragg scattering condition. For a monostatic radar, this condition requires the electron density to have structures matching half of the radar wavelength (e.g., 3 m for a 50-MHz radar). Neutral turbulence is ubiquitous in the mesosphere due to breaking gravity waves and dynamic instabilities. The turbulent eddies begin at scales of ~1 km, but cascade to progressively smaller scales until they become so small that viscosity becomes important. The spectrum of neutral turbulence is typically divided into an inertial subrange at the larger scales, where energy flows to progressively smaller scales without being destroyed, and a viscous subrange at the smallest scales where viscosity is removing kinetic energy from the turbulent eddies. The dividing line between the two subranges is near the Kolmogorov microscale, which is typically approximately 1–10 m in the mesosphere and increases with altitude. PMSEs are both intriguing and surprising because the 3-m irregularities responsible for Bragg backscatter at 50 MHz should lie within the viscous subrange of turbulence at 86 km and, as a consequence, should be strongly damped. Observations at higher frequencies indicate the presence of even smaller scales, which is even more puzzling.

Numerous different observations have demonstrated a link between PMSEs and the ice particles responsible for NLCs/PMCs. Rocket data of electron structure measurements in the medium provided the first clear indication that echoes were related to the coupling of electrons and small particles. Figure 8 shows simultaneous VHF scatter echo profiles and the electron

Figure 7 Observations of PMSEs from three different radars at different frequencies. For the two lower frequency radars, all of the observed strong signal is PMSE, but for the ultra high frequency (UHF) (300 to 3000 megahertz) radar (bottom panel), most of the signal is incoherent scatter from ambient D-region plasma. The UHF PMSE is visible as a small thin layer at 84 km at 1245 UT. After Rapp, M., Strelnikova, I., Latteck, R., et al., 2008. Polar mesosphere summer echoes (PMSE) studied at Bragg wavelengths of 2.8 m, 67 cm, and 16 cm. *Journal of Atmospheric and Solar-Terrestrial Physics* 70, 947–961.

density measured by the rocket during a strong event. A severe, sharp biteout in the latter is coincident with the echoing region. Biteouts like this have been observed by numerous rockets as well as by ground-based incoherent scatter radars. These biteouts form when dust or ice particles become charged by

collecting free electrons and thus are an indirect indication that these particles are present inside the PMSE layer.

Ice particles can be detected directly using optical techniques, since ice particles will scatter optical light. [Figure 9](#) is a simultaneous measurement of lidar and VHF radar

backscatter from the polar summer mesosphere. A lidar is a radar that uses laser light instead of radio waves. The lidar is sensitive to the largest ice particles, the same particles that can be viewed from the ground as NLCs. Notice that the lidar signal is at the lower edge of the radar signal, indicating that the radar

detects small particles as they fall, grow larger, and then are detected by the lidar just prior to sublimating as the temperature rises.

The occurrence of PMSEs in the summer polar mesosphere is undoubtedly linked to very cold temperatures. Simultaneous measurements of PMSEs with radar and of temperature with rockets showed that a sufficiently cold mesopause temperature is a necessary but an insufficient condition for the existence of PMSEs. A study of PMSE occurrence and low seasonal mesopause temperatures, the results of which are presented in [Figure 10](#), showed that the probability curve of seasonal PMSE occurrence in the Northern Hemisphere was similar to, but delayed by about 10 days from, a mean seasonal curve of low mesopause temperatures deduced from a number of measurements.

The cold mesopause/PMSE occurrence is further supported by measurements of PMSEs in the Southern Hemisphere at Machu Picchu station (62° S), which showed that PMSEs are much weaker and more sporadic in the Southern Hemisphere. One reasonable inference emerging from this observation is that the mean mesopause temperature at southern high latitudes is warmer than its northern counterpart. Indeed, preliminary examination of daily averaged summertime temperatures using satellite data (High Resolution Doppler Imager) at 84 ± 1.5 km suggests a few degrees of temperature difference between comparable summertime months found at 65° latitude, with the Southern Hemispheric temperatures being warmer. These results support previous indications of a warmer Southern Hemisphere from other satellite observations (Solar Mesosphere Explorer) when the temperatures were warmer in the Southern Hemisphere by about 4 K.

Another study supporting north-south asymmetries suggests that PMSEs can be detected at lower latitudes in the Northern Hemisphere than in the Southern Hemisphere, and it seems that PMSEs start occurring in an earlier stage in the south than in the north with respect to the solstice. These results could help in understanding why PMSEs were not detected late in the season at Machu Picchu station. Data collection at Machu Picchu station has not been possible earlier than late December for logistic reasons, thereby missing late November and early December observations when PMSE occurrence is supposed to start.

All of this discussion requires that PMSE generation somehow be associated with charged aerosols and, primarily, ice particles, suggesting that again, in addition to cold temperatures, water vapor is also necessary for PMSE generation. The differences between seasonal PMSE variation and temperature were speculated to be caused by water vapor.

Many mechanisms have been proposed as being responsible, or at least partly responsible, for PMSE generation. While it has been suggested that ice particles themselves scatter radio waves just as rain and snow enhance weather radar signals, such particles are too few and too small to create a huge signal. The observed echo strengths can only be generated by scattering from free electrons with a substantial amount of structure at the Bragg wavelength. One explanation for how such structuring could occur has received more theoretical attention and more observational evidence than any other: a modified version of turbulence theory that involves ambipolar diffusion.

Figure 10 Comparison of polar mesospheric summer echoes (PMSEs) percentage of occurrence at Poker Flat, Alaska, and various estimates of high-latitude seasonal mesospheric temperature fluctuations. Adapted from Balsley, B.B., Huaman, M.M., 1997. On the relationship between seasonal occurrence in northern hemispheric polar mesosphere summer echoes and mean mesopause temperatures. *Journal of Geophysical Research* 102, 2021.

Free electrons in the D-region ionosphere are structured by neutral turbulence because the electron-neutral collision frequency is so high that electrons essentially follow the neutrals at these altitudes. However, this does not mean that the electron density fluctuation spectrum must be identical to the kinetic energy turbulence spectrum. Ultimately, neutral viscosity limits the smallest scales that can form in the kinetic energy spectrum, whereas electron diffusion limits the smallest scales that can form in the electron density fluctuation spectrum. A commonly used dimensionless number is the Schmidt number, Sc , the ratio of viscosity of air to the electron diffusivity. If $Sc \sim 1$, the electron density fluctuation spectrum will be similar to the neutral kinetic energy spectrum (i.e., it will have clearly defined inertial and viscous subranges). When $Sc \gg 1$, however, the electron density fluctuation spectrum will be divided into three subranges. The largest scales will be in the inertial-convective subrange. Near the Kolmogorov microscale, the spectrum will transition to the viscous-convective

subrange. In this subrange, viscosity is important but diffusion is not. Finally, the spectrum transitions to the viscous-diffusive subrange and falls sharply. The dividing line between the viscous-convective and viscous-diffusive subranges is near the Batchelor microscale, which is smaller than the Kolmogorov microscale by a factor of $1/\sqrt{Sc}$. Thus, when $Sc \gg 1$ (i.e., when the electron diffusivity is anomalously low), the electron density fluctuation spectrum can be extended to much smaller scales than usual. To explain observations of PMSEs by UHF radars, Schmidt numbers of 3000–8000 are needed.

Diffusion of electrons in a plasma works differently from diffusion in neutral gases because the electrons are charged and thus coupled to all the other charged species in the plasma via electric fields. Consider a blob of plasma that is initially electrically neutral and composed of electrons and one type of ions. The electrons want to diffuse away much more quickly than the heavier ions, but if they did, they would

Figure 11 Simultaneous rocket measurements of a neutral kinetic energy spectrum (gray) and an ion density fluctuation spectrum (black) in the summer polar mesopause. The neutral spectrum shows a clearly defined inertial subrange at large scales ($k^{-5/3}$) and viscous subrange at small scales (k^{-7}). The ion spectrum shows a clearly defined inertial-convective subrange at large scales ($k^{-5/3}$), a viscous-convective subrange at intermediate scales (k^{-1}), and a viscous-diffusive subrange at small scales ($\exp(-k^2)$). Notice that the ion spectrum extends to much smaller scales than the neutral spectrum. After Strelnikov, B., Rapp, M., Zecha, M., et al., 2009. PMSE and E-region plasma instability: In situ observations. *Journal of Atmospheric and Solar-Terrestrial Physics* 71, 143–157.

leave behind a blob of ions with a net positive charge. An electric field forms, slowing the electron diffusion and accelerating the ion diffusion, and both species then diffuse together at the same rate. This field is known as the ambipolar electric field and the phenomenon is called ambipolar diffusion. Ambipolar diffusion is like a poorly trained dog that runs ahead and drags its owner along behind it while on a walk. In this analogy, the dog represents the electrons, the owner the ions, and the leash forcing the two to move together is the ambipolar electric field. The plasma in the polar summer mesopause is a three-component plasma consisting of electrons, ions, and charged dust or ice particles. Electrons and ions in such a plasma have two different ambipolar diffusion modes: a fast mode, close to the ion diffusion rate, and a slow mode, close to the dust/ice diffusion rate. **Figure 11** shows neutral and ion spectra measured by a rocket flying through a PMSE layer. The neutral spectrum has well-defined inertial and viscous subranges. The ion spectrum has well-defined inertial-convective, viscous-convective, and viscous-diffusive subranges. The ion spectrum is extended to much smaller scales than the neutral spectrum because of the slow ambipolar diffusion mode, which appears in the presence of charged dust/ice. The ambipolar mode can be so slow that the required Schmidt numbers of 3000–8000 for UHF PMSEs are reached if the ice particles have radii of 30 nm or more. Estimates from AIM and from ground-based multicolor lidar measurements have both observed ice particles with radii of 10–60 nm, meaning that the high Schmidt numbers required to explain UHF PMSEs using turbulence theory are readily obtainable.

On the Possible Relationship between PMSEs, NLCs, and Global Change

As time has passed, more observations of NLCs have been reported and an increasing trend has been detected. This increment in NLCs is explained by the observed increment in atmospheric methane (CH_4) and carbon dioxide (CO_2) due to human activity. A doubling increment in either of these components will produce a cooling of the thermosphere and mesosphere by about 50 and 10 K, respectively. Remember that cold temperatures are a necessary condition for NLC generation, although not the only one. About half of the mesospheric water vapor is believed to come from the photodissociation and oxidation of upwardly transported CH_4 with the chemically active radical (OH). Colder temperatures and more water vapor can produce more NLC events, so they can be used as indicators of global change.

The necessary conditions for PMSEs and NLCs or PMCs to occur appear similar: low temperatures are required and are apparently related to water vapor. The seasonal PMSE occurrence corresponds well with the high-latitude seasonal occurrence of NLCs. Recent studies have shown a correlation of PMCs with PMSEs in the Northern Hemisphere, where the mean long-term PMC occurrence ratio curve fits symmetrically inside the PMSEs occurrence ratio (**Figure 8**). A close correlation between NLCs and PMSEs has also been observed using lidar and radar data, respectively. These studies were made using a common volume and they agree most of the time. Thus, PMSEs are of particular interest in view of their frequent coincident occurrence with NLCs and the possible association of recent increased detection of NLCs with global warming trends. If we could monitor PMSEs for long periods and observe increases/decreases in these events (and their relative strength) over time, we could use such information as a possible indicator of global change.

PREFACE TO THE FIRST EDITION

A half century ago the American Meteorological Society published the *Compendium of Meteorology*, which in a single volume of 1334 pages summarized the state of understanding of the atmosphere at that time. A perusal of the contents of that volume indicates that although a broad range of topics was covered, the vast bulk of the volume was devoted to traditional meteorological topics such as atmospheric dynamics, cloud physics, and weather forecasting. Barely 4 percent of the volume was devoted to articles related to atmospheric chemistry or air pollution and, of course, none of the volume was devoted to techniques such as satellites and remote sensing.

As Sir John Mason aptly notes in his foreword to the present work, the atmospheric sciences have expanded in scope enormously over the past 50 years. Topics such as atmospheric chemistry and global climate change, of only marginal interest 50 years ago, are now central disciplines within the atmospheric sciences. Increasingly, developing areas within the atmospheric sciences require students, teachers, and researchers to familiarize themselves with areas far outside their own specialties. This work is intended to satisfy the need for a convenient and accessible references source covering all aspects of atmospheric sciences. It is written at a level that allows undergraduate science and engineering students to understand the material, while providing active researchers with the latest information in the field.

More than 400 scientists, from academia, government, and industry have contributed to the 330 articles in this work. We are very grateful to these authors for their success in providing concise and authoritative summaries of complex subjects. As editors, we have benefited from the chance to learn from these articles, and we believe that all students and active scientists who want to increase their knowledge of the atmosphere will benefit enormously from access to this work.

We are also grateful to the 31 members of the Editorial Advisory Board who have guided us in our coverage of the very broad range of topics represented in this encyclopedia. Their willingness to suggest topics and authors, and to carefully review draft articles has contributed significantly to our success.

The production of this multivolume encyclopedia would not have been possible without the dedicated work of the staff of the Major Reference Works group at Academic Press. We are especially grateful to the Major Reference Work Development Manager, Colin McNeil, who has worked closely with us during the entire process. Finally, we appreciate the liberal use of color figures in the printed encyclopedia.

James R Holton, Judith A Curry, and John Pyle

PREFACE TO THE SECOND EDITION

Since the publication of the first edition of the *Encyclopedia of Atmospheric Sciences*, significant advances in research have been achieved all across the broad and expanding spectrum of the field and related disciplines. In particular, climate science with primary input from the atmospheric research emerges as a new field and integrator of interlocking peripheral disciplines over the last decade. These events have demanded the solicitation of new and updated articles for the 2003 edition. Some articles from the earlier publication were judged to be of such a fundamental and enduring nature that they did not require modification. But huge amounts of new information from Earth-orbiting satellite observatories have brought much new insight to the field. In addition there are new findings in many areas such as the latest simulations of meteorological and climatic processes of interest as well as simulations and observations of the composition and interaction of the field's chemical constituents. While interest in the ozone hole and its ramifications may have reached a plateau, ever more understanding of the stratosphere and its role in climate change emerges. The study of past climates provides new means of testing climate models and theories. In weather prediction we see new progress on how data are to be better assimilated for much improved initialization of the forecast model leading to the promise of more accurate predictions of severe weather and tropical cyclones over longer lead times. These are just a few of the new features of the second edition.

The editors of the second edition are greatly indebted to our predecessors in the first edition. They set the outline of topics and solicited the original authors, while establishing a high standard for the content of this publication. In many cases we decided to reprint those articles or request only minor updates. Nevertheless, many articles in this edition are entirely original, based on which we also made significant reorganization of the content. We are proud of our product and hope it provides the same assistance to students, researchers, and practitioners throughout the science and engineering communities.

Editors of the second edition
Gerald R North
Fuqing Zhang
John Pyle

EDITOR BIOGRAPHIES

Gerald R North received his PhD in theoretical physics from the University of Wisconsin in 1966. After postdoctoral research at the University of Pennsylvania he became a faculty member in physics at the University of Missouri—St. Louis. He shifted his research focus to climate science research during his sabbatical year at the National Center for Atmospheric Research, where he won the Outstanding Paper Award in 1975. He moved to NASA Goddard Space Flight Center (GSFC) in 1978 where he was awarded the NASA Medal for Research Excellence. During his stay at GSFC, he was the proposer and first study scientist for the Tropical Rainfall Measuring Mission, which was launched in 1997 and is still orbiting in 2014.

He moved to Texas A&M University in 1986 as a university distinguished professor of atmospheric sciences where he served as department head from 1995 to 2003. He has served as editor-in-chief of the *Reviews of Geophysics* and is recognized as one of the most cited authors in geosciences (Web of Science). He has chaired and/or served on a number of national committees and is a Fellow of the American Geophysical Union, American Meteorological Society (AMS) and the American Association for the Advancement of Science, and winner of the Jule Charney Award for Research (AMS).

He has published about 150 refereed papers not including many book chapters and reviews. His books include *Paleoclimatology*, co-authored with Thomas Crowley, and *An Introduction to Atmospheric Thermodynamics* co-authored with Tatiana Erikhimova.

North's interests are focused on the use of mathematical and statistical tools to solve climate problems over a wide range of issues including: analytical solutions of simplified energy balance climate models, use of random field techniques in representing and interpreting climate data and model simulations, detection of deterministic signals in climate change, statistical analysis satellite remote sensing for mission planning and analysis of data, paleoclimate problems using simplified climate models.

John Pyle obtained a BSc in Physics at Durham University before moving to Oxford where he completed a DPhil in Atmospheric Physics, helping to develop a numerical model for stratospheric ozone studies. After a short period at the Rutherford Appleton Laboratory he moved to a lectureship at Cambridge University in 1985. In 2000 he was appointed professor of atmospheric science and since 2007 has been the 1920 professor of physical chemistry. He is a Professorial Fellow at St Catharine's College. He has been a codirector of Natural Environment Research Council's National Centre for Atmospheric Science, where he is currently Chief Scientist.

His research focuses on the numerical modelling of atmospheric chemistry. Problems involving the interaction between chemistry and climate have been addressed; these range from stratospheric ozone depletion to the changing tropospheric oxidizing capacity and have included the environmental impact of aviation, land use change, biofuel technologies, and the hydrogen economy. He has studied palaeochemistry problems as well as the projected atmospheric composition changes during the current century. He has published more than 250 peer reviewed papers.

He played a major role in building an EU stratospheric research programme in the 1990s, coordinating several major field campaigns. He has contributed to all the WMO/UNEP assessments on stratospheric ozone since the early 1980s and is now one of the four international cochairmen

of the Scientific Assessment Panel, responsible for these assessments. He was a convening lead author in the IPCC Special report "Safeguarding the ozone layer and the global climate system," published in 2006.

He was elected Fellow of the Royal Society in 2004 and an American Geophysical Union Fellow in 2011. He was awarded the Cambridge ScD degree in 2012. Other honours and awards include membership of Academia Europaea (1993), Royal Society of Chemistry (Interdisciplinary award, 1991, and John Jeyes lectureship, 2008), and the Royal Meteorological Society Adrian Gill Prize, in 2004.

Fuqing Zhang is a professor with tenure in the Department of Meteorology at the Pennsylvania State University, with a joint appointment in the Department of Statistics, along with an endowed position as the E Willard & Ruby S Miller Faculty Fellow at the College of Earth and Mineral Sciences at the Pennsylvania State University. His research interests include atmospheric dynamics and predictability, data assimilation, ensemble forecasting, tropical cyclones, gravity waves, mountain plains and sea-breeze circulations, warm-season convection, and regional-scale climate. He earned his BS and MS in meteorology from Nanjing University, China in 1991 and 1994, respectively, and his PhD in atmospheric science in 2000 from North Carolina State University.

He spent seven years as an assistant and then associate professor at Texas A&M University before coming to Penn State University as a full professor in 2008. In 2000, he spent a year and a half as a postdoctoral fellow at the National Center for Atmospheric Research. He also held various visiting scholarship appointments at various academic and research institutions including the National

Center for Atmospheric Research in Boulder, Colorado; the Navy Research Laboratory in Monterey, California; NOAA/AOML Hurricane Research Division, Miami, Florida; Peking University and Nanjing University, China; the Chinese State Key Laboratory of Severe Weather in Beijing, China; and Laboratoire de Meteorologie Dynamique, École Normale Supérieure in Paris, France.

He has authored/co-authored about 130 peer reviewed journal publications and has given more than 160 keynote speeches or invited talks at various institutions and meetings. He has served as principal investigator/co-principal investigator for 30 federal or state-sponsored research grants. He has chaired/cochaired more than 10 scientific meetings or workshops. He also served on various review or advisory panels for numerous organizations that include National Science Foundation, Office of Naval Research, NASA, NOAA, and National Academies. He has also served as editor of several professional journals including *Monthly Weather Review*, *Science China*, *Atmospheric Science Letter*, *Acta Meteorologica Sinica*, and *Computing in Science & Engineering*.

He has also received numerous awards for his research and service. Notably, in 2007 he received the **Outstanding Publication Award** from the National Center for Atmospheric Research. In 2009, was the sole recipient of the American Meteorological Society's 2009 **Clarence Leroy Meisinger Award** "for outstanding contributions to mesoscale dynamics, predictability, and ensemble data assimilation." Most recently, he received the 2014 American Meteorological Society's **Banner Miller Award** "for valuable insights into incorporating real-time airborne Doppler radar measurements via ensemble data assimilation, leading to improvements in forecasts of tropical cyclone track and intensity."

GUIDE TO USING THE ENCYCLOPEDIA

Structure of the Encyclopedia

The material in the encyclopedia is not arranged by ordinary alphabetical order, but by alphabetical order according to 49 principal topic areas taken to allow all papers belonging to each principal topic to appear together in the same volume. Within each principal subject, article headings are also arranged alphabetically, except where logic dictates otherwise. For example, overview articles appear at the beginning of a section.

There are four features that help you find the topic in which you are interested:

- i. the contents list
- ii. cross-references to other relevant articles within each article
- iii. a full subject index
- iv. contributors

i. Contents List

The contents list, which appears at the front of each volume, lists the entries in the order that they appear in the encyclopedia. It includes both the volume number and the page number of each entry.

ii. Cross-references

All of the entries in the encyclopedia have been cross-referenced. The cross-references, which appear at the end of an article as a See also list, serve four different functions:

- i. To draw the reader's attention to related material in other entries

- ii. To indicate material that broadens and extends the scope of the article
- iii. To indicate material that covers a topic in more depth
- iv. To direct readers to other articles by the same author(s)

Example

The following list of cross-references appears at the end of the article.

See also: **Biogeochemical Cycles:** Biogeochemistry of Iodine. **Stratospheric Chemistry Topics:** HO_x; Halogen Sources, Natural (Methyl Bromide and Related Gases); Halogens; Hydrogen Budget; Overview; Reactive Nitrogen (NO_x and NO_y).

iii. Index

The index includes page numbers for quick reference to the information you are looking for. The index entries differentiate between references to a whole article, a part of an article, and a table or figure.

iv. Contributors

At the start of each volume there is list of the authors who contributed to that volume.

Synopsis

Planetary waves are vertically propagating disturbances that are identified by large-scale variations in the pressure, temperature, winds, and composition. Much of the large-scale longitude variability in the middle atmosphere is due to planetary waves. They can be stationary or travel in longitude with periods of a few days to a few weeks. Planetary waves interact with other waves and with the background atmosphere. Large-amplitude waves can contribute to rapid changes in wind and temperature. Planetary waves also play a role in the impact of stratospheric changes on the troposphere.

Introduction

A planetary wave is a large-scale perturbation of the atmospheric circulation that extends coherently around a full longitude circle. The perturbations have wavelike forms in the longitudinal and vertical directions and often also in the latitudinal direction. These large-scale waves are a dominant part of the spatial and temporal variability in the stratosphere, and they also make contributions at higher altitudes in the mesosphere. Most important are quasistationary midlatitude Rossby waves, which propagate upward from the troposphere and are ubiquitous but quite variable in the middle atmosphere during winter. They are important because they have significant influence on the wind speed, temperature, distribution of ozone, and other characteristics of the middle atmosphere. Other planetary waves that are also important are global traveling modes, known as normal modes, and a class of waves confined to the equatorial region.

Much of the information about planetary waves in the middle atmosphere has come from measurements made by orbiting satellites. The type of measurement that has been most used is temperature profiles. The geopotential height profile

can be determined from the temperature profile using the hydrostatic relation if the geopotential height at some point along the profile (such as at the bottom) is known. Planetary wave information has also been determined from satellite observations of horizontal winds, especially in the mesosphere. Radiosonde, radar, and other ground-based observations, while not sufficient to determine global wave structure, provide important additional information about vertical structure. The data that have been used to construct the illustrations in this article were processed by the National Center for Atmospheric Research (<http://ncar.ucar.edu/>), Modern Era Retrospective Analysis for Research and Applications (MERRA; <http://gmao.gsfc.nasa.gov/research/merra/intro.php>), and Sounding of the Atmosphere Using Broadband Emission Radiometer (SABER; <http://saber.gats-inc.com/>).

Quasistationary Midlatitude Rossby Waves

Where they occur, planetary waves are evident in all dynamical fields: temperature, wind, pressure, and density. Observations of wave structure are commonly viewed using the temperature

or the geopotential height. Geopotential height is the height of a given pressure level. **Figure 1** shows the temperature and geopotential height for a pressure level in the middle stratosphere of the Northern Hemisphere on a particular day (10 hPa on 31 January 2007). The North Pole is at the center of each panel, and the equator is around the outer edge. The Greenwich Meridian is the horizontal line extending down from the pole. Colors indicate the temperature in Kelvin (upper) and the geopotential height in kilometers (lower) of the 10 hPa pressure surface. The variations are smooth compared with the much more abrupt variability seen near the Earth's surface on a typical weather map.

The planetary waves shown in **Figure 1** are the deviations from symmetry around a longitude circle. These can be decomposed further by performing Fourier analysis in longitude at a fixed latitude and pressure level. **Figure 2** illustrates the temperature and height variations and the results of Fourier analysis at 60° N. Both wave fields are dominated by zonal wave number 1, but wave number 2 also has significant amplitude. On a polar plot such as **Figure 1**, a wave number 1 pattern tends to be evident as a displacement of the lowest heights or temperatures off of the pole and sometimes, as in the case shown, as a distinct region of high height or temperature.

Figure 1 Polar stereographic projections (the North Pole is at the center, and the Equator is around the outer edge) of the temperature and geopotential height for the Northern Hemisphere at 10 hPa on 31 January 2007. Contours indicate the temperature in Kelvin or the height in kilometers. GM: Greenwich meridian.

Wave number 2 is evident as an elongation of the contours of the low-geopotential-height area.

For this day, pressure level, and latitude, the wave number 1 patterns in temperature and geopotential have similar phases. This is evident from the location of the maxima in **Figure 2** (both in the quadrant 90–180°) and also from the similar locations of the low temperature and low geopotential height in **Figure 1**. This is not always the case. **Figure 3** shows maps of the temperature and geopotential height for other pressure levels in the middle atmosphere. At 0.1 and 0.01 hPa, the longitude of low temperature is not near that of low geopotential height.

From geostrophic balance, air motion on a pressure surface tends to follow lines of constant geopotential height, with low values to the left in the Northern Hemisphere (counterclockwise flow around the low). One can see that following such a trajectory will move an air parcel alternately closer to the pole and farther from the pole. The time taken to complete a circuit of the pole depends on the latitude and wind speed, but it normally ranges from several days to longer than a week. The air parcel will also move vertically as it follows the circumpolar path, although the vertical excursions are much smaller than those in latitude, being typically on the order of 1 km.

Figure 4 shows the amplitude of wave numbers 1 and 2 for the case illustrated in **Figures 1** and **3**. Values at 10 hPa pressure correspond to the variations shown in **Figure 2**. Typical midlatitude Rossby waves vary in amplitude daily, but the longitude of the maximum geopotential height at a given pressure level often stays in the same quadrant. Several of the features evident in **Figure 4** are typical of wave amplitudes in the winter hemisphere. The geopotential height amplitudes are largest in middle to high latitudes near 60°; maximum amplitudes in the vertical are reached in the stratosphere, usually between 10 and 0.3 hPa, and wave number 1 has larger amplitude than wave number 2. The temperature amplitude has a minimum at the level where the geopotential height amplitude is largest. This case is atypical in that the wave number 1 amplitude is particularly large; more common values are about half of that seen on this particular day. Although planetary-scale waves have their largest amplitudes in the stratosphere, they do not disappear in the mesosphere (above ~0.3 hPa). Both temperature and geopotential height have measurable amplitudes up to the highest level shown (0.01 hPa, which is near 80 km altitude).

Figure 5 shows the variation of wave number 1 and 2 amplitudes during two Northern Hemisphere winters: 2006–07 and 2008–09. Wave amplitudes vary on a time scale of a few days. There are also large differences between different winters. Wave number 1 normally has higher amplitude than wave number 2, but exceptions have occurred, for example in January 2009. The amplitudes are not symmetric around the winter solstice. On average, the amplitude of wave number 1 is larger during January–February. The case in early 2009 is an exception; wave number 1's amplitude was small during January through March of that year.

Some of the Rossby waves generated in the troposphere by thermal contrasts between land and ocean surfaces and by flow over mountains propagate vertically and are the source of the midlatitude waves in the middle atmosphere. A substantial part of the variability seen in the wave amplitude (**Figure 5**) is

Figure 2 Variation of temperature and geopotential height with longitude and Fourier analysis showing the contributions of wave numbers 1 (solid) and 2 (dashed) at 60° N for the case shown in [Figure 1](#).

Figure 3 Polar stereographic projections of the temperature and geopotential height for the Northern Hemisphere at 1, 0.1, and 0.01 hPa on 31 January 2007.

Figure 4 The amplitude of wave numbers 1 and 2 of temperature and geopotential height as a function of latitude and pressure for 31 January 2007.

Figure 5 Variation of wave 1 and 2 geopotential height amplitude at 10 hPa with time, for the Northern Hemisphere winters of 2006–07 and 2008–09. Solid lines are wave number 1 amplitude, and dashed lines are wave number 2 amplitude.

a result of the variability of the large-scale weather patterns in the troposphere. With a few simplifications, it is straightforward to derive an equation that predicts which waves will propagate into the middle atmosphere. First, we split all fields into a zonal mean (longitudinal average) and perturbation

components and assume conditions of linearity, where the perturbation fields are significantly smaller than the zonal mean fields. The wave equation is derived from the perturbation form of the quasigeostrophic potential vorticity equation on a β -plane. In the β -plane approximation, the variation of Coriolis torque with latitude is assumed to be constant: $f(y) = f(y_0) + \beta(y - y_0)$, where f is the Coriolis torque and y is latitude. The quasigeostrophic potential vorticity equation is then given by eqn [1], where q , the quasigeostrophic potential vorticity, is defined in eqn [2].

$$\left(\frac{\partial}{\partial t} + \bar{u} \frac{\partial}{\partial x} \right) q' + v' \frac{\partial \bar{q}}{\partial y} = D \quad [1]$$

$$q = f + \frac{1}{f} \frac{\partial^2 \phi}{\partial x^2} + \frac{\partial}{\partial y} \frac{1}{f} \frac{\partial \phi}{\partial y} + \frac{f}{N^2} \frac{\partial}{\partial z} \rho \frac{\partial \phi}{\partial z} \quad [2]$$

The overbars in eqn [1] indicate zonal averages, and the primes indicate deviations from the zonal average. The planetary vorticity f has no perturbation component and is not included in q' . The zonal derivative $\left(\frac{\partial^2 \phi}{\partial x^2} \right)$ disappears for $\bar{q}$. $\bar{u}$ is zonal wind; v' is perturbation meridional wind; D represents damping due to diabatic processes, interaction with small-scale waves, and wave breaking; ϕ is the geopotential; N is the buoyancy frequency; ρ is the density; x is longitude; and z is altitude.

To solve eqn [1], we assume a waveform in the zonal dimension and in time, with wave number k and frequency ω or, equivalently, phase speed c , where $c = \omega/k$ (eqn [3]).

$$\phi' = \psi_k(y, z) \exp(ikx - i\omega t + z/2H) \quad [3]$$

Note that there is also an altitude factor $\exp(z/2H)$. This altitude factor takes into account the fact that a propagating, nondissipating wave will conserve energy, which is proportional to $|\phi'|^2$. With this conservation, the amplitude will increase with altitude because of the decrease in density (proportional to $e^{-z/H}$).

Substitution of eqns [2] and [3] into eqn [1] gives eqn [4], where Q is given by eqn [5].

$$\frac{\partial}{\partial y} \left(\frac{\partial \psi_k}{\partial y} \right) + \frac{f^2}{N^2} \frac{\partial^2 \psi_k}{\partial z^2} + Q \psi_k = D \quad [4]$$

where

$$Q = \frac{\bar{q}_y}{(\bar{u} - c)} - k^2 - \frac{f^2}{4H^2 N^2} \quad [5]$$

and

$$\bar{q}_y = \frac{\partial f}{\partial y} - \frac{\partial^2 \bar{u}}{\partial y^2} - \frac{f^2}{N^2} \frac{1}{\rho} \frac{\partial}{\partial z} \rho \frac{\partial \bar{u}}{\partial z} \quad [6]$$

H is the atmospheric scale height and N is the buoyancy frequency. Equation [4] is a two-dimensional wave equation when Q is positive (i.e., the solutions are sinusoidal in latitude and altitude). Note that the vertical and meridional scales are vastly different ($N \gg fN \gg f$; the ratio f^2/N^2 is typically 10^{-4}).

The restoring force responsible for the existence of planetary waves is provided by the zonal mean distribution of atmospheric angular momentum (or vorticity), which is determined

by the magnitude of Q . For a given zonal wave number k , the variations in Q are dominated by the meridional gradient of zonal mean potential vorticity $\bar{q}_y$ and the average wind speed $\bar{u}$. The strongest effect on the potential vorticity gradient is the gradient in planetary vorticity with latitude $\frac{\partial f}{\partial y}$, but its magnitude and sign can be significantly modulated by horizontal or vertical shear in the mean zonal wind. Outside of the tropics, $\bar{q}_y$ tends to be positive except for localized areas near the strongest wind shear.

The term Q can tell us quite a bit about the wave properties. Equation [4] has the form of a wave equation only when Q is positive. Since the background potential vorticity gradient $\bar{q}_y$ is usually positive, it is readily seen that the condition for propagation will not be met if the wind speed is less than the wave phase speed (or, for stationary waves forced by fixed features such as mountains, if the wind speed is less than zero). The locus of points where $(\bar{u} - c)$ goes to zero is known as the critical line. Normally, stratospheric winds are positive during winter and negative during summer, explaining the absence of the stationary planetary Rossby waves, for which $c = 0$, in the summer middle atmosphere when $\bar{u}$ is negative. Also note that there is a negative contribution that involves the wave number k^2 . For waves with larger wave numbers, this can become large enough that Q is negative. This explains why most Rossby waves observed in the middle atmosphere have low wave numbers (eqn [7]).

$$Q > 0 \Rightarrow k^2 < \frac{\bar{q}_y}{(\bar{u} - c)} - \frac{f^2}{4H^2N^2} \quad [7]$$

Q is also known as the refractive index squared, analogous to the geometrical optics property of the same name. Waves will be refracted in the latitude–altitude plane if there are gradients in Q . For example, for the case presented in Figure 4, Q increases toward low latitudes and has negative regions in high latitudes. Figure 6 shows contours of Q for zonal wave number 1 and, superimposed on this, arrows indicating the direction of propagation of the wave in the Northern Hemisphere's stratosphere. There is strong upward propagation in midlatitudes together with refraction toward the equator.

There is another way to look at these planetary waves that can shed light on how they interact with the background wind. Take the perturbation potential vorticity eqn [1], multiply it by the perturbation potential vorticity q' , and average zonally. This gives a conservation equation for the wave quantity q'^2 , which is the quasigeostrophic form of wave action (eqn [8]).

$$\frac{1}{2} \frac{\partial \overline{q'^2}}{\partial t} + \overline{v'q'} \frac{\partial \bar{q}}{\partial y} = \overline{q'D'} \quad [8]$$

It can be shown that the net poleward flux of potential vorticity, $\overline{v'q'}$, is proportional to the Eliassen–Palm (EP) flux divergence. The EP flux divergence is a quantity that is derived from the structure of the wave and is a precise measure of how the wave will force changes in the background atmosphere. A negative value of $\overline{v'q'}$, or equivalently of EP flux divergence, indicates that the wave is causing a negative acceleration of the background flow. In other words, the extent to which a wave can change the background average wind speed or temperature depends on $\overline{v'q'}$; if it is zero, the wave may be able to propagate

Figure 6 Contours of refractive index squared (Q) and vectors showing the direction and magnitude of energy propagation for wave number 1, for the case shown in Figure 4.

but will have no impact on the background atmosphere. From eqn [8], it is evident that $\overline{v'q'}$ will be nonzero only if the wave is not steady (first term nonzero) or is dissipating (right side of equation nonzero).

While eqn [8] is simple, its applications are important, and the phenomena it describes have a profound influence on middle-atmosphere circulation. In essence, a planetary wave will not influence the background temperature or winds and also will not cause any net transport of mass unless the wave is transient or is dissipating. In reality, planetary wave transience always occurs and dissipation can be significant, especially in the upper stratosphere and mesosphere. Planetary waves tend to reduce the wind speed and the strength of the winter-time vortex, to warm up the high-latitude stratosphere, and to induce transport of mass toward the winter pole and downward in the high-latitude stratosphere.

The largest amplitudes of planetary waves occur in the midlatitude upper stratosphere. At higher altitudes, dissipation becomes strong enough that the amplitudes begin to decrease with height. There are several processes that can dissipate the waves. The cooling by emission of heat (infrared radiation) is approximately proportional to temperature; warmer areas cool faster, thereby reducing the amplitude of the wave. Another important dissipation mechanism is interaction with small-scale waves. Propagation and dissipation of these small-scale waves will vary depending on the winds and temperatures of the planetary waves, and interactions will in turn affect the planetary wave structure. Small-scale waves and the turbulence produced by them become much more significant in the mesosphere (>60 km) and attenuate planetary waves that propagate to these levels.

As is evident from Figures 3 and 4, wave patterns are seen in both the stratosphere (from the tropopause up to about 0.03 hPa) and in the mesosphere (from 0.3 to the mesopause). Interactions of the large-scale dynamics with small-scale waves can damp wave structures but also generate waves. A planetary-scale variation in the small-scale waves that propagate into the mesosphere can exist due to planetary-scale variations in the generation of the small-scale waves. Another means of generating variations is through differences in the dissipation of the waves due to differences in winds, temperature, and so on. This means that planetary waves in the stratosphere can cause wavelike variations in the small-scale waves propagating to the mesosphere. When the small-scale waves dissipate and modify the dynamics in the mesosphere, they will generate a planetary wave pattern in the winds and temperature. The quasistationary planetary waves seen in winter above about 0.01 hPa probably contain a mix of propagating waves and wavelike variations due to interactions with small-scale waves.

Wave amplitudes also decrease toward low latitudes, even though the waves often propagate toward the equator. The waves cannot propagate where the refractive index squared is less than zero. As waves approach the low latitudes, they can undergo significant distortions as the normal restoring force associated with the polar gradient in potential vorticity $\bar{q}_y > 0$ begins to weaken. Since the wave itself can affect the potential vorticity, local regions where $q_y \leq 0$ will appear; air motion in such regions no longer experiences a restoring force but instead is unstable to perturbations in the north–south direction. Under these circumstances, there is a rapid and irreversible

Figure 7 The potential vorticity field corresponding to Figure 1.

deformation of the potential vorticity contours on a pressure surface, and the wave is said to ‘break,’ an analogy to the breaking of waves on a beach. Figure 7 shows the potential vorticity field corresponding to Figure 1. There is evidence of a broad region of weak or reversed latitudinal gradients of potential vorticity in the vicinity of 90° E and of deformation of the contour lines as tongues of high-potential-vorticity air are drawn out into the low-potential-vorticity region. This wrapping of contours is indicative of Rossby wave breaking. It leads to dissipation of planetary waves, primarily in low latitudes, and to horizontal mixing.

Occasionally, strong amplification occurs, and the wave has a sudden strong impact on the background wind and temperature. Extreme events can alter the temperature of the polar stratosphere by as much as 40 K in a week. The strongest of these events are known as major sudden stratospheric warmings, and they are one of the most dramatic examples in the atmosphere of the interaction of waves with the mean fields. In addition to increasing the temperature, the warming events also break down the polar vortex, redistribute ozone and other chemicals, and reverse the direction of the stratospheric jet in high latitudes. Major sudden stratospheric warmings occur during about half of the winters in the Northern Hemisphere.

Although the sudden warming events are rare, the processes that lead to them occur with smaller amplitude throughout a normal winter. Midlatitude planetary waves in general act to warm the polar regions and to slow the speed of the stratospheric jet. Planetary wave amplitudes tend to be larger in the Northern Hemisphere than in the Southern Hemisphere because of the different distributions of continents and orography. As a result, Southern Hemisphere stratospheric polar temperatures are cooler, and the vortex is stronger. From an observational record extending back to 1957, only a single major sudden stratospheric warming (in 2002) has been observed in the Southern Hemisphere.

Middle-Atmosphere Planetary Waves and Stratospheric Climate

The variability of the middle-atmosphere circulation is to a large degree controlled by wave motions that originate in the

troposphere. However, there is increasing evidence from observations and atmospheric modeling that the dynamical coupling between the troposphere and the middle atmosphere is a two-way process. While our understanding about this two-way coupling and its implications has increased considerably during the last two decades, the mechanisms by which changes in mean winds or planetary waves in the middle atmosphere can influence the tropospheric flow are still an important topic of current research.

As discussed in Section Quasistationary Midlatitude Rossby Waves, the middle-atmosphere background wind determines the propagation characteristics of upward-propagating planetary Rossby waves. Two mechanisms of downward coupling between the middle atmosphere and the troposphere can be identified. The nature of downward coupling depends on the vertical and meridional structure of the background wind, which either allows planetary waves to freely propagate within the middle atmosphere or acts like a vertical reflective surface that reflects wave activity downward.

There are specific configurations of the zonal mean flow that prohibit the upward propagation above a specific altitude in the free atmosphere (Section Quasistationary Midlatitude Rossby Waves, eqn [7]). During the summer months, planetary Rossby waves are generally trapped in the troposphere because of the easterly background flow of the stratosphere. During the winter and early spring, a reflective surface in the middle atmosphere can form when either (1) the mean zonal wind is less than the phase speed of the wave (i.e., $\bar{u} < c$), or (2) the meridional gradient in the potential vorticity becomes negative ($\bar{q}_y < 0$) above the jet maximum as a result of the decrease of the zonal mean wind with height above the jet peak. From eqn [6], it is evident that a large positive value of $\frac{1}{\rho} \frac{\partial}{\partial z} \rho \frac{\partial \bar{u}}{\partial z}$ can lead to a negative value of $\bar{q}_y$, and therefore to a reflecting surface. An upward-propagating wave that reaches a vertical reflective surface will be reflected and will then propagate downward into the troposphere. The reflected wave can modify the phase and amplitude of the tropospheric wave source.

The impact of wave reflection is illustrated using observations from a period during February 2000. Figure 8 shows a sequence of daily longitude $\times$ height cross-sections (from 0 to 360° and 700 to 1 hPa) of the zonal wave structure averaged between 50 and 60° N for the period from 5 to 13 February 2000. Strong changes in the propagation characteristics of a wave with zonal wave number 1 occur during this period. During this sequence, the mean zonal flow in the middle atmosphere is characterized by negative vertical wind shear of the westerly jet (not shown) causing the formation of a vertical reflective surface in the midstratosphere. Vertical wave propagation is characterized by a phase tilt of the wave field in the vertical plane. A westward tilt with height indicates upward propagation, and an eastward tilt indicates downward propagation. During the first 2–3 days in the daily sequence (Figure 8), the wave number 1 field exhibits a clear westward phase tilt with increasing height, illustrating that the wave is propagating upward. In the following days, the amplitude of the wave number 1 field in the stratosphere decreases. The most dramatic change is in the phase of zonal wave number 1 in

the troposphere and lower stratosphere (200–20 hPa). In this region, the wave moves westward beginning on 8 February. As a result of this shift, the wave number 1 phase then tilts eastward with height, suggesting downward propagation of the wave.

Planetary wave reflection is the most direct way by which the stratospheric background wind can affect the tropospheric circulation. However, another process of downward coupling, which also involves planetary waves in the middle atmosphere, is expected to cause more large-scale effects on the tropospheric flow. Planetary waves that propagate vertically change the middle atmosphere flow in winter midlatitudes when they grow large enough to break and be absorbed. The wind changes that result from the dissipating wave in turn shift the location of the region of strongest interaction of the waves with the mean flow. As a result of this shift, there is a downward and poleward progression of the location of the background wind disturbances, which can eventually reach the tropopause level. The strength of this interaction depends both on the strength of the tropospheric wave forcing and on the background flow itself. This process, which can cause long-lasting zonal wind anomalies at the tropopause level, is often accompanied by circulation anomalies all the way to the surface. The surface anomalies resemble a pattern called annular mode, which exhibits a hemispheric-scale spatial pattern of climate variability characterized by north–south shifts in mass between polar and lower latitudes. The mechanisms by which the long-lasting zonal wind anomalies at the tropopause resulting from wave mean flow interactions in the middle atmosphere are transmitted to the surface are still not well understood.

Normal Modes

Another class of waves that can be significant in the middle atmosphere is that of Rossby normal modes, also known as free modes. These are waves that correspond to natural modes of variability of the Earth's atmosphere. Based on the size and rotation rate of the Earth and the depth of the atmosphere, there are preferred responses. From eqn [5], it is clear that the restoring force Q depends on the phase speed of the wave c . In an undamped isothermal atmosphere ($D = 0$, $T = T_0$) with no background wind ($\bar{u} = 0$ and $\bar{q}_y = f$), there can exist global solutions to eqn [4] that are finite even without forcing. These are the normal modes, which can be considered to be resonances of the global atmosphere. The vertical structure of each mode can be determined from eqn [4] when damping is omitted and no waves are introduced by the boundary conditions. While these theoretical modes are the responses that would occur in an isothermal atmosphere without damping, the actual atmospheric conditions often allow for the existence of waves that are similar to the idealized modes. A perturbation to the atmosphere that excites a spectrum of waves can include one or more of these normal modes, which then grow in amplitude with height due to the decrease in density.

A number of these modes have been identified theoretically for realistic conditions. They can reach large amplitudes in the middle atmosphere. One commonly observed mode is

Figure 8 Longitude-height cross-sections of zonal wave one geopotential height (m) averaged between 50 and 60° N for the daily temporal sequence from 5 to 13 February 2000. Positive and negative values are in red and blue, respectively; zero values are in black. The isoline interval is 50 m.

the quasi-two-day wave, which has a period of about 2 days and a zonal wave number of 3 or 4. It is regularly observed in the mesosphere just after solstices and can attain very large amplitudes (meridional wind $\sim 30 \text{ m s}^{-1}$). Two modes with zonal wave number 1 also appear regularly, although they have smaller amplitudes: the 16-day wave, most commonly seen in the winter hemisphere, and the 5-day wave. These waves do not transport much momentum and do not

normally have a major direct impact on the global momentum balance in the stratosphere. However, they can interact with other waves such as quasistationary Rossby waves, gravity waves, and tides and thereby affect the periodicity of variability in the middle atmosphere. Because of its slow phase speed, the 16-day wave is a significant component of the atmospheric response to quasistationary disturbances.

Equatorial Waves

Another class of planetary waves occurs only near the Equator. These rely on both buoyancy forces and the conservation of potential vorticity, and they are not represented by eqn [1]. Of these, the most commonly observed in the middle atmosphere is the Kelvin wave, which is regularly seen in satellite observations with high vertical resolution. A theoretical Kelvin wave in the β -plane approximations has no meridional winds. Its structure can be determined from the momentum and thermodynamic equations under simplified conditions ($\bar{v} = v' = \bar{w} = D' = 0$). Again, we assume a waveform with zonal wave number k and frequency ω and also assume a vertical wave number m (eqn [9]).

$$\phi' = \phi_k \exp[i(kx + mz - \omega t) + z/2H] \quad [9]$$

The governing equations can then be written as eqns [10]–[12].

$$-(\omega - k\bar{u})u' + k\phi' = 0 \quad [10]$$

$$\beta y u' + \phi'_y = 0 \quad [11]$$

$$k u' - (\omega - k\bar{u}) \frac{m^2}{N^2} \phi' = 0 \quad [12]$$

Eliminating u' from eqns [10] and [11] gives the meridional structure of the wave (eqn [13], where ϕ_0 is the wave geopotential at the equator).

$$\phi' = \phi_0 \exp \left[-\frac{\beta k y^2}{2(\omega - k\bar{u})} \right] \quad [13]$$

Figure 9 shows the latitudinal structure of geopotential and zonal wind for an idealized Kelvin wave.

A range of Kelvin waves have been observed. All are traveling waves that move eastward with time. They have wave perturbations in temperature and zonal and vertical winds; the meridional winds associated with the wave are zero. Kelvin waves with low zonal wave numbers (waves 1–3) have the largest amplitudes. Some Kelvin waves have periods of 24 h and are therefore also classified as atmospheric tides.

Equations [10] and [12] can be combined to give a dispersion relation (eqn [14]), which relates the frequency of the wave (ω) to the zonal (k) and vertical (m) wave numbers. The wave

numbers have units of inverse length and are related to the wavelengths of the wave; for example, the vertical wavelength is $2\pi/m$. Lower-frequency waves will have larger vertical wave numbers or, equivalently, short vertical wavelengths.

$$(\omega - k\bar{u}) = \frac{-Nk}{m} \quad [14]$$

Low-frequency Kelvin waves that take 10–20 days to propagate around the globe occur in the lower stratosphere but are not able to propagate deep into the middle atmosphere. Eventually, they are likely to encounter a critical level when the background zonal wind speed is equal to the phase speed of the wave ($\omega - k\bar{u} = 0$), and the wave can no longer propagate. The tropical stratospheric winds are characterized by temporal variability associated with the quasibiennial (QBO) and semiannual (SAO) oscillations. The locations of the critical levels change with time owing to these oscillations in $\bar{u}$. Higher frequency Kelvin waves can propagate through the stratosphere and sometimes as high as the upper mesosphere. The deeper propagation is possible because their phase speeds exceed wind speeds that are found at lower levels (i.e., they do not encounter a critical level). Propagation is also facilitated because the faster phase speeds are associated with larger vertical group velocities and are less effectively damped.

Another equatorial mode is known as the mixed Rossby-gravity wave. This mode propagates westward and has been observed in the stratosphere. Although the mixed Rossby-gravity wave is, like the Kelvin wave, an equatorially trapped traveling wave, it has some key differences. It propagates westward and has finite meridional wind. In some ways, mixed Rossby-gravity waves and Kelvin waves in the stratosphere are complementary because they tend to be seen in different wind regimes, have zonal phase speeds in opposite directions, and carry zonal momentum of opposite signs.

When a wave encounters a critical level, where $\omega = k\bar{u}$, it can no longer propagate. The momentum carried by the wave will be absorbed at or near that point and will alter the background wind speed. Kelvin and mixed Rossby-gravity waves will propagate upward (Kelvin waves through easterly winds, and mixed Rossby-gravity waves through westerly winds) only until they reach a critical level. Mean zonal wind speeds in the equatorial stratosphere, and hence also the locations of critical

levels, oscillate with time on seasonal to interannual time scales, in connection with the SAO and QBO. The momentum deposited at that point actually alters the evolution of these oscillations. The QBO is believed to be driven to a large extent, and the SAO in part, by the momentum deposited by these tropical waves.

Synopsis

The polar vortex refers to a region of the winter polar stratosphere characterized by high nearly zonal westerly winds and isolation from the rest of the stratosphere and the extreme cold temperatures within the vortex that allows for cloud formation and the complex chemistry of rapid ozone loss to occur in late winter and early spring. The polar vortex extends from the tropopause, (8–11 km in altitude), to the stratopause (50–60 km in altitude). Above the stratopause the zonal winds reverse. The Southern Hemisphere (SH) polar vortex is much stronger than the Northern Hemisphere (NH) vortex due to the absence of large-scale waves – planetary waves – in the SH. Planetary waves disrupt the vortex producing a short period circulation reversal known as a Major Stratospheric Sudden Warming. Major sudden warmings occur about every other year during the NH winter, but, due to the lack of planetary wave activity, they are very rare in the SH winter. The only observed SH sudden warming occurred in 2002. The polar vortex forms in fall and persists through winter into spring at which point it breaks up giving rise to the easterly summer circulation. The breakup of the polar vortex in the spring is called the final warming. The final warming occurs near the spring equinox in the NH, but occurs 1–2 months later in the SH. There is good evidence that the Antarctic ozone depletion has produced to a more persistent SH polar vortex. The spring vortex breakup date is now late November rather than late October as was observed in the 1970–80s.

The polar vortex is the region of high-atmospheric vorticity that forms with the establishment of the winter stratospheric polar jet (Figure 1). The polar jet begins just above the tropopause in both the Northern and Southern Hemispheres reaching maximum wind speeds near the stratopause (~50 km). The polar jet arises from the strong temperature contrast between the warm tropical stratosphere and the cold polar stratosphere. The tropical stratosphere is heated by the ozone ultraviolet absorption. The polar winter stratosphere is unheated during

polar night and cools through infrared emission to space principally by the gases carbon dioxide, ozone, and water. The resultant equator to pole temperature difference creates a strong pressure gradient and, as air moves northward, the Coriolis force deflects this air eastward, creating a strong eastward-flowing jet. Above the stratopause, the temperature gradient between the tropics and the polar region reverses, and polar night jet speed decreases with altitude into the mesosphere. The winter polar vortex is seen in both hemispheres,

Figure 1 Contours of the wintertime zonal mean zonal (west-east) wind in m s^{-1} for July in the SH (left) and January in the NH (right) based upon 1979–2010 Modern Era Retrospective-Analysis for Research and Applications or MERRA data set (Rienecker, M., et al., 2011. MERRA: NASA's modern-era retrospective analysis for research and applications. *Journal of Climate* 24, 3624–3648. doi:10.1175/JCLI-D-11-00015.1). The log-pressure height ($7 \log(1000/p)$ km) is shown on the left with pressure in hPa on the right. The stratosphere is the region above the tropopause (indicated with the solid white lines). The polar vortex is the region poleward of the strong stratospheric wind jet. The dotted white lines indicate the locations of the cross sections shown in Figure 2.

but the Southern Hemisphere (SH) winter vortex is significantly stronger and longer lasting than its Northern Hemisphere (NH) counterpart. The polar jet almost completely isolates the polar vortex from the mid-latitude stratosphere. This vortex isolation along with the heterogeneous chemical processing on stratospheric clouds creates the conditions for severe polar ozone depletion over the winter poles. The linkage of the polar vortex to the ozone depletion has generated considerable interest and research into the formation and breakup of the polar vortex. Below we review the development, evolution, and breakup of the polar vortex. We also review sudden stratospheric warmings and the differences between the NH and SH vortices.

Formation of the Polar Vortex

The polar vortex begins to form after the fall (autumnal) equinox when solar heating of the polar ozone layer is cut off with the onset of polar night. Without solar heating, infrared (IR) cooling of the polar air mass causes temperatures to fall and air begins to descend over the polar region. By continuity, air also flows poleward as the polar jet intensifies (*see Radiation Transfer in the Atmosphere: Absorption and Thermal Emission; Scattering*). The polar vortex usually becomes well organized as a strong zonal (East-West) flow by mid-November. **Figure 2** shows the evolution of the vortex zonally or longitudinally with averaged wind speed at 50 hPa (~ 20 hPa). Satellite data obtained by the Halogen Occultation Limb Experiment aboard the Upper Atmosphere Research Satellite first showed that a significant amount of mesospheric air enters the stratosphere during the formation phase of the polar vortex. Subsequent model calculations showed that this descent was in agreement with radiative transfer theory. Polar air parcels in the midstratosphere may descend a scale height or more (~ 7 km) during the formation of the vortex. At lower altitudes, the descent is not as large, but this vortex formation period is an important mechanism for the return of air from the middle and upper stratosphere to the lower stratosphere. Because air from the upper stratosphere contains a lower concentration of organic chlorine relative to inorganic chlorine, the descending circulation enriches the inorganic chlorine content of the polar vortex and is a factor in the severity of polar ozone depletion.

The Mature Vortex

In most years, the NH polar vortex winds reach peak intensity during mid-January. It is during this period that polar stratospheric temperatures reach their lowest values. From 20 to 25 km, temperatures approach 190 K, and clouds form in the lower stratosphere. At an altitude of about 20 km the vortex has an area of 2.1×10^7 km² (2.9×10^7 in the SH). **Figure 3** shows the midwinter climatology of the NH and SH polar vortices. While the SH vortex is nearly symmetric, the NH vortex is distorted. Streamlines are displaced poleward in the North Pacific and over the Aleutian islands by an anticyclonic anomaly. This feature is sometimes called the Aleutian anticyclone.

Figure 2 (Middle) Time–latitude diagram of the zonal mean wind speed at 50 hPa (~ 20 km) (see the horizontal dotted line in **Figure 1**). The top of the image has been shifted 6 months (July to June) with respect to the bottom (January to December) to emphasize the differences between the midwinter flow. Both polar jets begin to intensify just before equinox and continue to grow in strength reaching a peak in mid- to late-winter (January in NH, August in SH). (Top) 60°N Time–height cross sections and (Bottom) 60°S Time–height cross sections. Again, the 60°N cross section is shifted by 6 months for comparison. The vortex winds intensify at highest altitudes first and the isotachs appear to descend as the vortex intensifies later at lower altitudes. The NH vortex reaches peak wind speeds, on an average, between in mid-December and in mid-January. The SH vortex reaches peak wind speeds about 2 months after winter solstice.

Figure 3 Streamlines of the monthly mean wind flow (white arrows) along with the structure of the vortex (Ertel's potential vorticity) on the 500 K isentropic surface (~ 20 km altitude) for the SH (left) and NH (right). The thickness of the streamlines denotes the wind speed. Note that the SH vortex is stronger (higher values of potential vorticity) and is more symmetric around the pole. The potential vorticity is computed using winds and temperatures from a 33-year average of the MERRA stratospheric analyses.

Sudden Stratospheric Warmings

The strong zonal winds of the polar vortex provide a channel for the upward propagation of Rossby waves from the troposphere. Charney and Drazin (1961) first derived a dispersion relation for vertically propagating Rossby waves and showed that only the planetary-scale waves ($\lambda > 6000$ km) could penetrate the strong westerly polar vortex winds during winter. Synoptic scale Rossby waves ($\lambda < 6000$ km), responsible for most of the tropospheric variability, would be trapped in the troposphere. Planetary-scale Rossby waves (planetary waves for short) are principally forced by airflow over topography,

although they can also arise from longitudinal variations in thermal forcing or nonlinear interaction between short-scale waves. The stationary zonal harmonic one planetary wave seen in Figure 3 displaces the polar vortex away from the North Pole. This planetary wave is linked to the flow over the Himalayan Plateau. As planetary waves propagate into the stratosphere, they tilt westward with altitude and distort the longitudinally symmetric structure of the vortex. As viewed from an observer hovering over the pole, the circumpolar jet appears to be offset from the pole, or elongated across the pole. As these waves move, it appears as if the vortex is wobbling (see Figure 4). These wobbles can grow so large that the vortex is

Figure 4 Sudden warming in the Northern Hemisphere is shown in this sequence of potential vorticity plots on the 500 K potential temperature surface (~ 20 km). The projection is polar orthographic (North Pole is at the center). The sequence begins with the vortex displaced off the pole by the Aleutian anticyclone. The vortex elongates, rotates, and finally splits into two fragments over the period of about 1 month.

completely pulled off of the pole so that the zonal mean midlatitude temperature gradient is reversed. This condition is called a sudden stratospheric warming and is relatively common in the NH. In 2002, the SH produced its only observed sudden warming. **Figure 5** shows the vortex structure and the streamlines for a series of dates during this September 2002 major warming. A warming disrupts the vortex and fragments of the vortex move to extrapolar latitudes. For example, the 5 October panel of **Figure 5** shows a long streamer of air that has broken off of the polar vortex following the warming and now extends westward from the vortex (about 40° E to about 90° W).

The World Meteorological Organization definition of a major sudden stratospheric warming requires a winter zonal mean wind reversal at 10 hPa. A rapid decrease in wind speed but without a reversal in the temperature gradient is called a minor warming. A stratospheric warming is not considered an instability of the vortex since none of the usual atmospheric instability conditions are met (see **Middle Atmosphere: Stratospheric Sudden Warmings**).

Sudden stratospheric warmings appear to descend from higher altitudes. Modeling studies have pointed to critical layer interaction as the mechanism for this descent. A critical layer is a region where the zonal mean wind speed is equal to the zonal phase speed of a propagating wave. An upward-propagating large-scale planetary wave increases in amplitude (as measured by the geopotential anomaly, for example) with increasing altitude as the atmospheric density decreases. Eventually, the

flow becomes so highly distorted in the upper atmosphere that the wave can no longer propagate and the wave energy and momentum are ‘dumped’ into the flow as a wave-breaking event. The strong nonlinear wave–mean flow interaction takes place at the ‘critical level’ for the stationary planetary wave or the zero zonal wind speed contour. The sudden warming disturbance appears to move downward because the secondary circulation driven by the wave interaction with the critical level extends below the level of wave breaking, decelerating the mean flow below the wave-breaking zone. The extension of the secondary circulation associated with wave breaking below the level of wave breaking is sometimes called ‘downward control.’ As the critical level moves downward, the planetary wave breaks at much lower altitudes hence the sudden warming appears to descend. A similar mechanism is responsible for the descent of the alternate easterly and westerly winds in the tropics that is called the Quasibiennial Oscillation. As the stratospheric warming penetrates into the troposphere, it can cause a shift in the climatic patterns.

A sudden warming can develop in any reasonable stratospheric numerical model that allows upward planetary wave propagation and that is forced by a planetary wave with increasing amplitude at the lower boundary. What is not understood is what causes the planetary wave amplitude to increase rapidly. Some studies have suggested that resonance-type instabilities may be responsible for the amplification. A more descriptive approach has also been useful in understanding the development of the sudden warming as shown in

Figure 5 A sequence of streamline and potential vorticity maps display the only major stratospheric warming observed in the historic record of the Southern Hemisphere (500 K potential temperature surface, ~20 km). Note how the early map is relatively symmetric about the pole, but is highly distorted into a planetary wave-2 structure by 24 September. By 5 October, the polar vortex has moved back onto the South Pole, but winds are greatly weakened over this 19-days period. The weakening of the winds and vortex is accompanied by a large temperature increase in the stratosphere.

Figure 4. If the vortex is perturbed from a zonally symmetric position, the strong winds will begin to transport low-potential vorticity (PV) air from the tropics toward the polar region. The tropical air, which has an anticyclonic vorticity, tends to further increase the vortex displacement from the pole. Continued forcing from below causes the vortex to dip further toward the tropics and further increases the northward transport of anticyclonic air. This process continues amplifying the anticyclone generating the sudden warming event. Subsequent to the displacement of the vortex from the pole, elongation of the vortex often creates two zones where anticyclonic air can be transported northward, and a secondary ridge forms subsequently splitting the vortex in two. When the vortex is displaced

off the pole, the dominant planetary wave is zonal harmonic one. With the strong vortex winds disrupted, the poleward transport of very-low-PV air weakens, and radiative cooling of the polar air causes downward transport of high-PV air from the mid- and upper stratosphere, reestablishing the polar vortex. Depending on the time of year and altitude, the recovery usually takes a few weeks as is dictated by the IR cooling rates in the lower stratosphere. Sudden stratospheric warmings are most common in mid- to late winter, but they have been observed as early as December in the NH. From the mid-1950s to 1991, major warmings occurred about every other year, but between 1992 and 1998 there were no major warmings. A spectacular December 1998 major warming broke this lull.

Figure 6 The final warming in the NH (a) and SH (b) at the 500 K potential temperature surface (~ 20 km). Although each year is slightly different, these 2 years typify the process. Final warmings mark the breakup of the polar vortex and the onset of the summer circulation. The appearance of a triangular pattern in the SH is not surprising since planetary wave three is forced by topography. Final warmings in the NH occur around equinox, whereas final warmings in the SH may be more than 2 months after the equinox (note the difference in the vortex duration shown in [Figure 2](#)).

Transport across the Polar Vortex Boundary

The size of the polar vortex can be measured by a number of methods. The most common is to use the contour of the peak in the PV gradient. This gradient region is seen in [Figure 4](#) as the strong transition from the higher PV (red) to lower PV values (blue). After reaching maturity in midwinter, the polar vortex area begins to decrease. This erosion process occurs as planetary waves pull PV off the vortex edge, often into spectacular filaments associated with sudden warmings. One such filament is visible in the lower left corner of the second map in [Figure 4](#). High-resolution simulations of the vortex show that the vortex is always shedding smaller filaments of vorticity. The erosion of the vortex is continuous, but it is most rapid during sudden stratospheric warmings. This erosion process mixes vortex air into the midlatitude air (see 5 February 1979, [Figure 4](#)). Occasionally, the atmospheric circulation forces midlatitude air into the interior of the vortex, but this process rarely happens above 100 hPa (16 km). Thus, the polar vortex tends to isolate vortex air from midlatitude influence, with the vortex edge acting as a mixing barrier. The isolation of the polar vortex air from midlatitude air is a key factor in the development of polar ozone depletion. Without the isolation, the high concentration of ozone-destroying chemicals could not be sustained. Below 100 hPa, the polar vortex is less organized and intrusions from the tropical troposphere are often seen. However, because air is descending within the vortex during winter, these intrusions do not affect the chemistry above 100 hPa.

Breakup of the Polar Vortex

The polar vortex typically lasts until the spring equinox in the NH and up to 2 months or more past the spring equinox in the SH. Solar heating of the polar ozone layer increases toward equinox, thus reducing the ability of the strong IR cooling to restore the temperature gradient. As during midwinter, the strong planetary activity in spring disrupts the vortex, but the warmer stratospheric temperatures that follow the warming are much closer to the radiative equilibrium temperature. Thus no strong diabatic descent of high-PV air follows the event and the vortex does not recover. This event is called the final warming. After the final warming, the circulation in the zonal mean winds remains as easterlies in the lower stratosphere, signaling the onset of the summer circulation. Fragments of the chemically perturbed vortex air mass may persist throughout the summer and have been observed in the lower stratosphere. [Figure 6](#) shows the sequence of events that lead to a final warming in the NH and SH, respectively. These dates are typical for each hemisphere, although final warmings may be later or earlier by 15 days or so.

Differences between the NH and SH Vortices

The SH polar vortex forms more rapidly, is stronger, covers a larger area, persists longer than the NH vortex ([Figure 3](#)), and, unlike its boreal counterpart, shows little year to year variability in strength ([Figures 1](#) and [2](#) middle and bottom

panels). The stronger vortex is due to the lack of planetary wave activity in the SH. This lack of wave activity is due to the relative flatness of the SH in comparison to the large-scale continental topographic features of the NH. Indeed, some of the strongest SH planetary wave features are not stationary but traveling waves. Major midwinter stratospheric warmings have been observed only once in the SH since 1979. The paucity of SH warmings is a result of weaker poleward eddy heat flux, and this weak poleward heat flux leads to a much weaker poleward and downward circulation over Antarctica. This dynamically driven downward circulation warming warms the polar stratosphere. Its absence results in much colder vortex temperatures and polar stratospheric clouds form over wide regions, giving rise to the more severe Antarctic ozone depletion. The persistent nature of the Antarctic polar vortex is also a result of a lack of planetary wave activity that can erode the Antarctic vortex. Historically, the Antarctic vortex was observed to last until about a month after spring equinox (the NH vortex lasts until around spring equinox). More recently, the lower stratospheric Antarctic vortex has been observed to persist until late November. This persistence is likely due to the ozone loss within the vortex interior, which reduces the solar heating after equinox and slows the rise of polar stratospheric temperatures. Ozone depletion also takes place within the NH vortex, but no convincing evidence yet exists that this depletion has had an effect on the timing of breakup of the NH polar vortex.

Synopsis

Interannual variability of winds and temperatures in the lower and middle tropical stratosphere is dominated by the quasi-biennial oscillation (QBO). The QBO is characterized in rawinsonde observations by slowly descending easterly and westerly wind regimes, with each cycle of the oscillation lasting 2–3 years. Concentrations of ozone and other trace gases are modulated by the QBO, and its influence also extends during winter to higher latitudes in the stratosphere, and to some degree also into the troposphere.

Introduction

The quasi-biennial oscillation (QBO) of the equatorial lower and middle stratosphere is a fairly regular 2- to 3-year cycle characterized by alternating descending regimes of easterly (westward propagating) and westerly (eastward propagating) zonal wind (Figure 1). Accompanying the zonal wind QBOs are anomalies of temperature, trace constituents, and mean meridional circulation. The QBO dominates the equatorial lower and middle stratosphere and affects other regions of the atmosphere, including the tropical troposphere, tropical upper stratosphere and mesosphere, and the extratropical middle atmosphere in winter.

The QBO is more regular than El Niño/Southern Oscillation (ENSO), but is not biennial or otherwise exactly synchronized with the seasonal cycle. The oscillation is, however, modulated by the seasonal cycle in one or more ways. Onset of new QBO westerly regimes in the middle stratosphere is linked to descending westerly phases of the stratopause semiannual oscillation (SAO) (see **Middle Atmosphere: Semiannual Oscillation**). Not all SAO phases initiate a new QBO phase, obviously, since the period of the QBO is 4–6 times that of the SAO. New phases of the QBO aloft generally wait for old phases of the same sign to decay in the lower stratosphere and disappear. Below 30 hPa, the seasonal cycle modulates the final descent of old QBO phases (Figure 2). This seasonal effect is distinct from that of the SAO and is likely caused by annual cycles of upwelling and of wave fluxes entering the stratosphere from below.

The QBO period is unrelated to any known periodic forcing and is therefore difficult to understand, but we should not overlook the regular nature of the oscillation. The predictability of the QBO is remarkable, considering that wave motions responsible for the QBO (described below) occupy a broad spectrum of spatial and temporal scales, are episodic, complicated, and inherently unpredictable. The oscillation has now been observed by regular radiosonde soundings for more than half a century (26 complete cycles), with fairly constant amplitude, and by all appearances is a permanent feature of the tropical stratosphere.

QBO of Mean Zonal Wind

The prominent aspect of the QBO is an oscillation of mean zonal wind, where ‘mean’ refers either to a zonal average of

data spaced uniformly around a latitude circle or to a time average of soundings at an individual rawinsonde station (typically averaged over 1 month). Zonal or temporal averaging eliminates most high-frequency waves in the tropical stratosphere. However, not all zonal asymmetries are eliminated by time averaging. Quasi-stationary planetary waves propagate from the winter hemisphere into the middle and upper equatorial stratosphere and mesosphere. Monsoon circulations originating in the tropical troposphere penetrate the lowermost tropical stratosphere. It is unknown whether these zonally asymmetric motions are an important part of the QBO, i.e., to what extent the QBO departs from perfect zonal symmetry. The traditional view of the QBO as a zonally symmetric phenomenon is accurate enough to provide a basis for theoretical, numerical, and experimental studies of the oscillation.

The QBO is the dominant component of mean-flow variability in the equatorial lower stratosphere, and is approximately symmetric about the equator. The annual cycle of mean zonal wind is approximately antisymmetric and is easily removed from the data by subtraction of the climatology. The SAO attains measurable amplitude in the tropical middle stratosphere, and dominates the upper stratosphere and lower mesosphere. There is also a ‘mesopause SAO’ out of phase with the stratopause SAO. Both SAOs are affected by the underlying QBO.

Details of the wind oscillation are as follows. The QBO attains maximum amplitude of about 23 m s^{-1} on the Equator, between 30 and 10 hPa, diminishing in amplitude above and below this layer. The amplitude of the zonal wind QBO is approximately zero at the tropical tropopause ($\sim 17 \text{ km}$). The latitudinal profile of zonal wind amplitude is Gaussian-like with e-folding scale of $14\text{--}15^\circ$ (Figure 3). The phase of the zonal wind QBO is independent of latitude in the tropics, except that (1) the onset of westerly acceleration on the equator occurs about a month before its onset at adjacent off-equatorial latitudes, and (2) QBO extrema in the middle stratosphere are displaced a few degrees off the equator into the winter hemisphere. There is a pronounced asymmetry between easterly and westerly phases. The maximum value of westerly wind ($\sim 15 \text{ m s}^{-1}$) is about half that of the maximum easterly wind ($\sim 30 \text{ m s}^{-1}$). The descent of westerlies from 10 to 70 hPa is more rapid and uniform than the descent of easterlies. Easterly shears occasionally stall above 50 hPa; most stalls occur between July and February (e.g., during 1988 and 1989 in Figure 1). As

Figure 1 Time–height cross section of monthly mean zonal wind near the Equator, obtained from rawinsonde data at three locations. Data obtained from Freie Universität Berlin. Contour interval 5 m s^{-1} , with westerlies red and easterlies blue. Right vertical axis shows the approximate altitude. Red vertical lines and text indicate the rawinsonde stations from which each portion of the data is taken.

a result, QBO westerly (easterly) regimes are of longer duration than QBO easterly (westerly) regimes at 50 (10) hPa.

Easterly onsets at 50 hPa cluster in the northern late spring and early summer (Figure 2). The duration of easterly phases is typically about 12 months at this level, so westerly onsets also cluster at this time of year. Several onsets fall outside this broad time interval; hence, the QBO is modulated, but not synchronized, by the seasonal cycle. It is likely that if the seasonal cycle did not exist, the QBO would be completely asynchronous. Similarity between the average period of the QBO (~ 28 months) and integral or half-integral multiples of

the annual cycle (24 or 30 months) is coincidental. The period of the oscillation cannot be explained by the seasonal cycle.

Theory of the QBO

A theory of the QBO must account not only for its unusual period but also for equatorial westerlies in ‘superrotation,’ extending over a deep layer, without loss of amplitude from 10 to 50 hPa. A rotating atmosphere, at rest with respect to the surface, has maximum absolute angular momentum at the

Figure 2 Seasonal distribution of QBO phase initiations at 50 hPa, defined as the first month of new easterly (E, left) or westerly (W, right) zonal wind phase. Numbers in the boxes indicate the year of the phase transition.

Figure 3 Latitudinal profiles of zonal wind amplitude for annual, semiannual, and QBO cycles at 30 hPa, derived from rawinsonde data. Symbols show results from individual stations, at a variety of longitudes. Solid curves were obtained from station data averaged in 2° latitude bins.

equator. Equatorial westerlies imply a larger value of absolute angular momentum, which cannot be obtained through advective rearrangement of angular momentum from a state at rest. Either superrotation must exist a priori, or momentum transport by zonally asymmetric motions is required. Equatorial westerlies exist in the SAO westerly phase, but it is unlikely that QBO westerlies are derived entirely (if at all) from SAO westerlies. It is theoretically possible for SAO westerlies to be advected downward at the equator by an anomalous diabatic circulation, but to conserve absolute angular momentum

(weighted by mass) the zone of westerlies would become much narrower than observed, and the rate of descent would be much slower. This statement, incidentally, is based on conservation of angular momentum and differs from a linear-diffusive model of zonal wind propagation described in early QBO literature. Of course, SAO westerlies also require explanation. It is thought that momentum transport by zonally asymmetric wave motions is responsible for descending easterly and westerly phases of the QBO, and for descending westerly phases of the stratopause SAO. These waves consist primarily of large-scale Kelvin, Rossby-gravity waves, inertia-gravity waves, and small-scale gravity waves.

Momentum transport by vertically propagating waves is one of two essential ingredients in a simple theory of the QBO. The other ingredient is a mechanism for switching between QBO phases at lower levels. As shown schematically in Figure 4, a spectrum of easterly and westerly waves, also propagating vertically, spontaneously create descending easterly and westerly shear zones. Momentum transported vertically by the waves is irreversibly deposited in the mean flow as the waves break or are dissipated, e.g., by radiative damping. Dissipating waves in general tend to accelerate the mean flow in the direction of their horizontal phase propagation. Given a small asymmetry in the wave spectrum propagating up from below (or a small nonzero mean flow, if the forced wave spectrum is symmetric about zero phase speed), waves of one sign will drive the mean flow in the lower part of the domain, leaving the upper part free to accelerate in the opposite direction, owing to waves with phase speed of opposite sign. There is a limiting value of mean flow that can be attained through this mechanism for any fixed spectrum of wave forcing. Thus, in order to conserve angular momentum, shear zones must descend with time. This process continues until (1) the lower shear zone cannot descend any farther, and (2) the upper shear zone descends to immediately above the lower jet. At this point, a switching mechanism is required for any further change in the mean flow. Most models assume that vertical diffusion of momentum provides such a switching mechanism, causing the lower jet to decay. Then, waves responsible for the lower jet are free to propagate vertically and create a new shear zone at upper levels. The entire process repeats, with shear zones reversed, until the lower jet (now of opposite sign) is once again destroyed by diffusion. Waves of opposite sign then propagate to upper levels, forming a new shear zone, and so on, resulting in a perpetual 'nonlinear oscillation.' The period of oscillation is determined by several

Figure 4 Conceptual model of the QBO, illustrating the vertical propagation and mean-flow acceleration due to eastward and westward waves (large arrows) and tendency due to vertical diffusion of momentum (small arrows). Panel labels (a) through to (d) indicate the temporal progression of the oscillation; see text for further explanation. After Plumb, R.A., 1984. The quasi-biennial oscillation. Holton, J.K., Matsuno, T., (Eds.), *Dynamics of the Middle Atmosphere*. Terra Scientific, Tokyo.

factors, including the total wave flux input at the lower boundary, the range of mean wind speeds attained by wave driving, and the amount of atmospheric mass affected by the oscillation. This model easily accounts for the QBO's asynchronous period, superrotation, downward propagation without loss of amplitude, and tendency for new phases to begin aloft as old phases decay at lower levels. It should be noted that the wave forcing is felt within each descending shear zone, so that the oscillation is, as it were, continually forced. The QBO, therefore, should not be regarded as a freely propagating, zonally symmetric wave. In this context, the 'lower boundary' of the QBO corresponds to the tropopause, with wave excitation occurring in the tropical troposphere.

It is likely that vertical mixing of momentum occurs intermittently or continuously within descending shear zones as a result of shear instabilities arising from the superposition of intense mean shear ($\sim 10 \text{ m s}^{-1} \text{ km}^{-1}$) and large-amplitude wave motions. Vertical shear observed in the QBO and SAO is the largest of any mean flow in the terrestrial atmosphere. The mean shear by itself, however, is insufficient for shear instabilities that require the local Richardson number to fall below $1/4$.

This conceptual model of the QBO is attributable to Richard Lindzen. In a 1968 paper coauthored with James Holton, the first numerical simulations of the QBO were described. At the

time, Lindzen's assertion regarding the role of waves did not have much observational support. The idea was intuitive, derived from (1) the known theoretical properties of gravity-wave momentum transport and critical-layer absorption (*see Dynamical Meteorology: Critical Layers*), (2) speculation that the necessary wave fluxes existed in the tropical atmosphere, and (3) the assumption that a suitable mechanism for phase switching could be found. Observational evidence of equatorial Rossby-gravity waves and Kelvin waves (*see Tropical Meteorology and Climate: Equatorial Waves*) began to accumulate in the later 1960s. It soon became evident that wave fluxes were quantitatively in the right ballpark, so there was little reason to doubt the Lindzen-Holton theory. This evidence was exploited by Holton and Lindzen to construct a modified theory in which the QBO is driven by two waves: a radiatively damped Kelvin and Rossby-gravity wave, rather than by critical-layer absorption of a broad spectrum of gravity waves. The basic QBO mechanism was unchanged.

Results of a laboratory experiment by Alan Plumb and Angus McEwan published in 1978 provided compelling evidence that an oscillation similar to that predicted by theory can occur in a weakly viscous nonrotating fluid as a result of momentum transport by vertically propagating internal gravity waves.

Today, it is thought that additional wave fluxes are required, beyond those of the Kelvin and Rossby-gravity waves, primarily because the entire oscillation occurs in a region of slow ascent due to the Brewer–Dobson circulation. The rates of mean ascent and QBO descent are comparable, but opposite in sign. A simple estimate suggests that about twice as much momentum flux is required, relative to the value without upwelling, to sustain a similar QBO. This additional flux is likely provided by a broad spectrum of gravity and inertia-gravity waves whose role in the QBO can be simulated reasonably well using the original Lindzen–Holton model. Recent observations of ascending water vapor anomalies in the equatorial lower stratosphere were used by the author to calibrate a simple QBO model, suggesting that the required total wave flux is two to four times as large as that of large-scale equatorial Kelvin and Rossby-gravity waves.

Considerably more work remains to be done to obtain a detailed picture of the wave spectrum. This problem is a challenging one because actual wave motions are spatially localized and episodic in time, occupying a wide range of spatial and temporal scales. Much of the relevant wave activity in the tropical stratosphere is attributable to deep moist convection in the tropical troposphere, which is irregular from day to day and also characterized by strong regional and seasonal variations.

Tropical Effects of the QBO

Accompanying the zonal wind QBOs are temperature anomalies (~ 4 K) in thermal wind balance with the zonal wind anomalies. Westerly (easterly) vertical shear is relatively warm (cold) and requires anomalous subsidence (upwelling) to maintain the temperature anomaly against radiative damping (Figure 5). The resulting circulation anomalies affect the dynamical QBO. Subsidence in westerly shear enhances the descent rate and vice versa. The QBO's mean meridional circulation may also limit the latitudinal extent of the oscillation. The example shown in Figure 5 was obtained from

Figure 5 Temperature and mean meridional circulation anomalies associated with the QBO in February 1994, obtained from UK Met Office data. Contour interval 0.5 K, starting at this value, with values less than -0.5 K shaded. Adapted from a diagram by Bill Randel.

observations in late winter 1994. At solstice, the circulation pattern is asymmetric about the Equator, with a stronger winter cell. The QBO circulation at equinox is more symmetric.

For photochemically active trace species whose mixing ratio depends directly or indirectly on temperature, there is a QBO anomaly of mixing ratio sharing the same pattern and cross-equatorial symmetry as temperature. Ozone in the middle and upper stratosphere is photochemically controlled and provides a good example. Long-lived species such as methane, water vapor, and nitrous oxide, on the other hand, illustrate the effects of the QBO circulation anomaly. Ozone in the lower stratosphere, under dynamical control, can also be regarded as a long-lived tracer. Phase differences between QBO circulation and constituent anomalies depend on the rate of destruction by eddy mixing and photochemistry.

It has been known for several decades that column ozone is affected by the QBO. For this constituent, and for many other tracers, the relation to the dynamical QBO is somewhat difficult to understand, particularly at off-equatorial latitudes where the seasonal cycle and QBO overlap. Here, tracer anomalies are more synchronized with the seasonal cycle than is the dynamical QBO, and their temporal spectra contain additional frequencies (periods near 21 and $8\frac{1}{2}$ months) representing the nonlinear interaction of annual cycle and QBO. An example is shown in Figure 6, for methane in the middle stratosphere. A possible explanation of the ‘quasi-synchronized’ pattern of tracer anomalies in the subtropics is that the QBO’s influence is felt more strongly at a certain time of year (e.g., late winter or early spring) than at other times of year. The subtropical pattern cannot remain constant, because the relation between the QBO and annual cycle changes from one year to the next. Rather, there is a slow modulation of the subtropical pattern. The modulation period is equal to the time required for QBO onsets to march through a calendar year: e.g., 13 years, for a QBO period of 26 months. During a modulation cycle, the maximum amplitude of subtropical tracer anomaly may switch from one hemisphere to the other, and back again.

Temperature and circulation anomalies affect trace constituents directly, through photochemistry and advection. An indirect effect of the QBO is to modulate the lateral propagation and isentropic mixing due to planetary waves entering the tropics from the winter hemisphere. QBO easterlies ensure that a critical layer for quasi-stationary planetary waves is located in the winter hemisphere, well off the Equator, isolating the equatorial stratosphere from mixing due to planetary-wave breaking. QBO westerlies, on the other hand, allow quasi-stationary waves to penetrate the tropics and possibly break there, affecting the momentum balance of the QBO and the distribution of trace constituents. Modeling has shown, however, that equatorial mixing does not necessarily occur in the westerly phase. Breaking of small-amplitude waves occurs off the Equator, in both hemispheres, where the mean zonal wind is minimum. Large-amplitude waves have a wider critical layer, which may overlap the equator and cause mixing there. These two situations seem relevant to the QBO. At 50 hPa, where planetary waves are relatively small, QBO westerlies are long lived (12–18 months) without attenuation. At 10 hPa, where the waves are larger, QBO westerlies are short lived. This asymmetry could be due to the vertical propagation of an

Figure 6 Time–latitude cross section of methane anomalies in the middle stratosphere, obtained from the Halogen Occultation Experiment instrument, reconstructed from the leading four Empirical Orthogonal Functions (EOFs) of deseasonalized data. Contour interval 0.03 ppmv, with negative values shaded.

asymmetric wave spectrum, or to the asymmetry of induced mean meridional circulation. There is evidence, however, that laterally propagating waves also determine the onset of QBO easterlies at 10 hPa.

The combined effects of mean circulation advection and isentropic mixing are illustrated in **Figure 7**, showing a latitude–height cross section of nitrous oxide in early 1992 obtained from the Cryogenic Limb Array Etalon Spectrometer instrument aboard the Upper Atmosphere Research Satellite. The upper part of the ‘staircase’ pattern of tracer isopleths is attributable to an asymmetric QBO circulation anomaly similar to that shown in **Figure 5**. QBO westerlies in the

middle and upper stratosphere at this time overlay easterlies in the lower stratosphere, and a subtropical westerly jet had formed near 30° N. Between this jet and the Equator was a narrow zone of mixing by planetary waves, visible in tracer maps, acting to homogenize the constituent field in this region. Similar isentropic mixing was evident in the midlatitude ‘surf zone’ at lower levels. The phase of the dynamical QBO was reversed 1 year later, along with the tracer anomalies, and there was little evidence of isentropic mixing in the tropical upper stratosphere.

Other effects of the QBO in the tropical atmosphere include a modulation of SAO westerly descent, with westerlies

extending to progressively lower levels as the QBO westerly phase decays. Easterly phases of the mesopause SAO are stronger in the QBO deep westerly phase. The QBO is prevented from entering the tropical troposphere, owing to the Hadley circulation, but some effects of the QBO have been reported in this region also. The QBO may affect the latitudinal distribution of sea-level pressure, precipitation, and deep convection. Analysis of QBO-related variability in the tropical troposphere is complicated by unrelated biennial variability in this region. From the 1950s to 1980s, the QBO was believed to influence the occurrence of Atlantic hurricanes, but this relationship appears to have vanished as the observational record has lengthened.

Extratropical Effects of the QBO

The extratropical middle atmosphere undergoes a strong seasonal cycle, with a complete reversal of mean zonal wind and mean meridional circulation between summer and winter. Quasi-stationary planetary waves propagate vertically in mean westerlies that prevail during winter, and effects of the QBO on the extratropical middle atmosphere are observed primarily during this period (i.e., from late autumn to early spring). During January, mean zonal winds poleward of 45° N are stronger by about 10 m s^{-1} in the QBO 50 hPa westerly phase, relative to the easterly phase at this level (Figure 8(a)). A similar effect is seen in other winter months, although the signal tends to weaken in late winter (e.g., in March). This anomaly represents a strengthening of the stratospheric polar vortex (note the climatological wind contours shown in Figure 8(a)), and is accompanied by more intense planetary-wave activity and flux convergence at high latitudes in the 50 hPa easterly phase, which occur slightly earlier in winter (November through January). Stratospheric major warmings in the polar lower stratosphere, which occur in about half the

winters, are somewhat more likely in the easterly phase of the QBO. There is also some evidence that the QBO's influence on the polar lower stratosphere in late winter depends on the phase of the solar cycle. The 'normal' effect of the QBO described above is seen in years near solar minimum, while near solar maximum the effect is absent or perhaps reversed. There is some debate over the robustness of this solar modulation of QBO influence, but unlike in the aforementioned case of Atlantic hurricane activity, evidence of this effect is present in the observational record up to the present day. In addition to the solar cycle, there is also evidence that QBO influence on the polar vortex can be modulated by ENSO. Model studies focusing on the extratropical effect of the QBO unanimously agree with the observed tendency for more disturbed conditions and weaker mean zonal winds when the QBO in the lower tropical stratosphere (e.g., at 50 or 40 hPa) is in the easterly phase. The mechanism is not well understood, but may involve nonlinear reflection of planetary waves from a subtropical critical layer. The zero wind line is a critical surface for stationary planetary waves, and as noted in the previous section, it is displaced poleward in the easterly QBO phase, forming a narrower waveguide and resulting in more intense wave activity at high latitudes. The effect of the QBO is gradual, accumulating through a winter season, leading to a divergence of behavior between easterly and westerly phases of the QBO.

The models robustly suggest that the extratropical effect of the QBO is greatest in an intermediate range of planetary-wave forcings. At small amplitude, planetary waves have little effect on the circulation, and the QBO's influence is small. At large amplitude, planetary waves disrupt the polar vortex irrespective of the phase of the QBO. In Northern winter, planetary-wave amplitudes lie in an intermediate range, allowing the QBO's effect to be seen throughout much of the winter. In Southern winter, wave amplitudes are smaller, and the QBO's effect at high latitudes is delayed until early spring. At this time of year

Figure 8 (a) Composite of mean zonal wind in January, showing the difference between westerly and easterly phases of the QBO at 50 hPa in January. For reference the climatological zonal wind is shown in line contours (contour interval 10 m s^{-1}) using the same color scheme, with thicker lines for larger values, and the gray line indicating the zero wind contour separating stratospheric winter westerlies from summer easterlies.

Figure 9 Extratropical surface signature of the QBO during northern hemisphere winter, shown by the January 1000 hPa geopotential height (Z1000) westerly minus easterly QBO composite difference, with QBO phase defined by 50 hPa QBO winds in January (as in [Figure 8\(a\)](#)). Contour interval 5 m, with positive anomalies red and negative anomalies blue. For reference the climatological Z1000 is shown in line contours (contour interval 75 m), with thicker lines for larger values.

the Antarctic ozone hole forms. The severity of ozone loss is affected by the QBO, with greater depletion in westerly QBO years when the air inside the polar vortex is colder and the vortex westerly winds are stronger. [Figure 8\(b\)](#) illustrates this effect for November, when the transition from winter westerlies to summer easterlies is in progress (as indicated by the climatological wind contours shown in [Figure 8\(b\)](#)). The equatorial QBO modulates a mode of variability in high northern latitudes known as the Arctic Oscillation or Northern Annular Mode (NAM). The NAM is closely related to polar vortex

warming events and propagates downward from the stratosphere to polar troposphere, implying a possible link between the QBO and high-latitude tropospheric circulation in winter. The surface manifestation of this link during January is shown in [Figure 9](#). The NAM pattern, which in its positive phase is characterized by low pressure at high latitudes surrounded by a ring of higher pressure at midlatitudes, is evident in [Figure 9](#). The signal is strongest in the Atlantic region, where it resembles the North Atlantic Oscillation (NAO) pattern. The NAO has a strong effect on weather conditions in this region, and its apparent link with the QBO may provide a useful source of NAO predictability on seasonal timescales.

Semiannual Oscillation

K Hamilton, University of Hawaii, Honolulu, HI, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The dominant feature of the large-scale circulation near the equatorial stratopause is a strong semiannual oscillation in the prevailing winds. The stratopause zonal winds oscillate from strong easterlies around the time of the solstices to westerlies around the equinoxes. A similar oscillation, but exactly out of phase, is observed near the mesopause. The zonal wind oscillation is accompanied by similar semiannual variations in temperature and in the mean vertical motion.

Introduction

Regular observations of the winds and temperatures in the low-latitude stratosphere began only in the 1950s. Such observations were limited initially to operational balloon-borne radiosondes, which normally have a maximum ceiling of about 30 km (pressure of about 10 hPa). Once several years of such observations were available, it was clear that the variations in near-equatorial winds in the stratosphere below 30 km were dominated by a somewhat irregular oscillation with a mean period of roughly 28 months – what we now know as the quasibiennial oscillation (QBO).

Rocket observations of the winds extending to altitudes significantly higher than the balloon ceiling began in the mid-1960s at a small number of tropical stations. The black curves in [Figure 1](#) show the composite seasonal cycle of the zonal wind at several levels from the midstratosphere to the stratopause determined from many years of rocket observations at two near-equatorial stations. The result clearly displays the QBO in the

Figure 1 The long-term mean zonal wind each month of the year at different levels above Ascension Island (8S, 14W) and Kwajalein (9N, 168E). Black curves show observations from rocketsondes; red curves show observations from global reanalysis data. The vertical distance between the axes at successive levels represents 40 m s⁻¹. middle stratosphere, but also shows that the QBO becomes much less prominent above about 5 hPa (~35 km altitude), where it is replaced as the dominant signal by a strong semiannual oscillation (SAO) with peak-to-peak amplitude exceeding 50 m s⁻¹ near 1 hPa (~50 km altitude). Near the stratopause, the phase of the SAO is such that maximum easterly anomalies occur shortly after the solstices in January and July, while the maximum westerly anomalies occur around April and October.

Observations

As noted in this article, the discovery of the SAO was based on *in situ* observations from sondes launched by rockets. In recent years, these direct observations of the wind have been supplemented by gridded global reanalysis data that use all the available observations, including satellite determinations of temperature together with a sophisticated simulation model of the atmosphere. The red curves in [Figure 1](#) show the seasonal composite from many years of the reanalysis data produced by the European Centre for Medium Range Weather Forecasts (ECMWF). The ECMWF reanalysis also shows the SAO in the wind and compares reasonably well with direct observations. [Figure 2](#) is a height–time section of the seasonal composite of the equatorial zonal–mean zonal wind from many years of the ECMWF global analyses plotted from the ground up to 0.1 hPa (~65 km altitude). The phase and amplitude of the SAO are seen to vary systematically with height. Notably, there is a downward propagation of the wind reversals reminiscent of the behavior of the QBO. There is also some annual (12-month) variation evident in the wind results in [Figure 2](#). Near the stratopause, the SAO cycle in the first half of the calendar year is significantly stronger than that in the second half of the year.

Data from all available rocketsonde stations have been used to produce the plot of the amplitude of the semiannual harmonic of zonal wind, as a function of height and latitude shown here as [Figure 3](#). The dominant meridional modulation is a falloff in SAO amplitude away from the equatorial region, although there is an indication of a somewhat larger amplitude on the southern side of the equator.

The *in situ* observations of the wind in the upper stratosphere and lower mesosphere are limited to the rocket soundings, which are available from only a small number of stations, and the useful wind data are very sparse at low latitudes. The SAO is also seen in temperature observations, and,

in particular, the stratopause SAO has been observed in remote-sensing radiometer measurements of temperature from several different satellites. The equatorially trapped and roughly zonally symmetric aspects of the SAO near the stratopause appear clearly in these satellite temperature observations, as does the second equatorial maximum near the mesopause. The zonal-mean zonal wind and temperature are expected to be in approximate thermal wind balance (see **Dynamical Meteorology: Overview**), implying that, when there is westerly shear

on the equator, the mean temperature should drop off with latitude to both the north and south. Thus, westerly (easterly) shear regions in the SAO should correspond to anomalously warm (cold) temperatures centered on the equator. The available observations of the wind and temperature SAO do appear to be consistent with this expectation. As an example, **Figure 4** shows the equatorial zonal-mean temperature at several levels near the stratopause determined for each month of the year by averaging available remotely sensed satellite observations over

Figure 4 Climatological seasonal march of zonal-mean equatorial temperature at several levels in the upper stratosphere: 1 hPa (~ 50 km), 1.5 hPa (~ 48 km), 2.2 hPa (~ 45 km), and 3.2 hPa (~ 42 km).

several years. The seasonal march of these temperatures at each level is dominated by the SAO, and the downward phase propagation is evident.

In the upper mesosphere and lowermost thermosphere, the available *in situ* rocket data are extremely limited, although there are enough wind measurements to suggest that a second maximum in SAO amplitude occurs near the mesopause. Fortunately, at these heights, satellite-based remote-sensing observations of the horizontal wind (based on measurements of the Doppler shifts of atmospheric line spectral emissions) are available. **Figure 5** shows the zonal-mean zonal wind at the

equator as a function of time of year and height between 65 and 110 km, determined from several years of these satellite measurements. The strong SAO in the 75–90 km altitude range is easily seen. A similar pattern has been observed in low-latitude ground-based radar observations of the wind at these heights.

Dynamics of the SAO

The fact that a strong SAO in atmospheric circulation should occur near the equator is not, in itself, surprising. The sun

Figure 5 Composite seasonal cycle of the zonal-mean zonal wind at the equator based on several years of data from satellite remote sensing. The contour interval is 10 m s^{-1} , and dashed contours indicate easterly winds. crosses the equator twice each year, and the seasonal cycle of the daily-mean solar radiation incident on the atmosphere is dominated by a semiannual harmonic at low latitudes. However, it has been a significant challenge to account for all the observed features of the SAO. The occurrence of easterly mean wind extremes around the solstices at the stratopause level can be accounted for in terms of the annual modulation of the large-scale circulation in the meridional plane. In particular, at stratopause levels, the large-scale flow is thought to proceed from the summer hemisphere (where air is rising in the extratropical stratosphere) into the winter hemisphere (where air sinks in the extratropics) (*see Middle Atmosphere: Transport Circulation*). Consistent with this flow is a large-scale structure of the zonal wind field with strong easterlies in the summer hemisphere and westerlies in the winter hemisphere (*see Middle Atmosphere: Zonal Mean Climatology*). The effect of the cross-equatorial flow is to advect the summer easterlies onto the equator, and this effect should peak twice a year, roughly around or just after the solstices (when the cross-equatorial flow is strongest).

The westerly mean flow accelerations in the stratopause SAO are thought to arise largely from the interaction of the mean flow with vertically propagating internal gravity waves or large-scale equatorial waves generated in the lower atmosphere (*see Gravity Waves: Overview; Tropical Meteorology and Climate: Equatorial Waves*). The mutual effects of (1) the mean flow on wave propagation and (2) wave momentum transport on the mean flow lead to a pattern of downward-propagating mean jets (*see Dynamical Meteorology: Wave Mean-Flow Interaction; Middle Atmosphere: Quasi-Biennial Oscillation*). In the lower stratosphere, this is observed in both phases of the QBO, and the downward propagation is particularly characteristic of the westerly acceleration phase of the stratopause SAO (*Figure 2*).

Simple numerical models of the mean flow in the low-latitude middle atmosphere that have incorporated representations of these two mechanisms (a seasonally independent source of gravity waves or equatorial waves to account for the westerly acceleration, and the semiannually modulated effects of cross-equatorial momentum advection) have been able to simulate realistic stratopause SAO behavior. Also, these two mechanisms have been shown to operate in some comprehensive general circulation models (*see Numerical Models: General Circulation Models*) that extend into the middle atmosphere and produce somewhat realistic SAO simulations. However, there still remain some significant uncertainties concerning the stratopause SAO dynamics, including such issues as the relative role of higher frequency gravity waves versus lower frequency, large-scale equatorial waves, and the possibility of significant effects on the equatorial mean flow from stationary planetary waves (*see Dynamical Meteorology: Stationary Waves (Orographic and Thermally Forced)*) forced in the extratropics.

The uncertainties concerning the dynamics of the strong SAO near the mesopause are even greater. One plausible explanation for the mesopause SAO is that the mean wind variations of the stratopause SAO act as a filter for a broad spectrum of eastward- and westward-propagating gravity waves excited in the lower atmosphere. When there are strong westerlies at the stratopause level, the upward propagation of waves with westward phase speeds into the mesosphere is favored. When these waves are absorbed at higher levels, they will produce easterly mean flow

accelerations (*see Dynamical Meteorology: Wave Mean-Flow Interaction; Middle Atmosphere: Quasi-Biennial Oscillation*). Thus, this filtering effect leads naturally to a mean flow oscillation at higher levels that is 180° out of phase with the stratopause SAO. Once again, this mechanism has been included in simple numerical models that have produced a reasonably realistic SAO in the simulated mesopause mean flow. However, observations of the relevant wave-mean flow interactions in the real atmosphere sufficiently detailed to quantitatively confirm this mechanism are not available.

Effects on Trace Constituents

The SAO in zonal wind and temperature should be accompanied by an SAO in mean circulation in the meridional plane. The SAO variations in zonal-mean vertical velocity are much too small to be measured directly, but the accumulated effects can be seen in the distribution of the concentration of long-lived trace constituents in the stratosphere and mesosphere. As noted in this article, the occurrence of westerly shear on the equator is accompanied by anomalously warm temperatures at low latitudes. Associated with these warm temperatures will be anomalously high radiative cooling rates, and either sinking of air or at least anomalously weak rising motion near the equator.

The effects of the SAO appear clearly in observations of the zonal-mean concentration of long-lived trace constituents such as nitrous oxide (N_2O) and methane (CH_4) in the stratosphere. Both N_2O and CH_4 have chemical sources in the troposphere and are lofted into the stratosphere in the mean tropical upwelling. These constituents are subject to chemical destruction in the stratosphere, and this leads to a vertical stratification in the concentration (*see Stratospheric Chemistry Topics: Overview*). The SAO of rising and depressing the mixing ratio distribution, leading to a semiannual cycle of trace constituent concentration near the equator.

Synopsis

This article reviews the history, dynamics, and impacts of stratospheric sudden warmings. Sudden warmings are the most dramatic meteorological phenomenon in the stratosphere and affect the distribution of trace constituents in the stratospheric and tropospheric weather.

Introduction

The stratospheric sudden warming (SSW) is the most dramatic meteorological phenomenon to take place in the stratosphere. This article will describe its main features and will give a brief history of its discovery. Examples of the various kinds of SSW will be presented and discussed. There is then a review of some of the theoretical ideas that have been advanced to explain the origin and evolution of the SSW. This includes a discussion of what triggers the SSW and what factors might affect the frequency at which it occurs. Finally, the effects of SSWs are considered, first on the distribution of trace constituents in the stratosphere, and secondly on the weather.

The Basic Facts

SSWs occur in the stratosphere of the Northern Hemisphere during winter. Temperatures rise sharply, by as much as 80 °C or more in a few days. Figure 1 shows temperature changes recorded at a high-latitude location during a strong sudden warming. Accompanying these changes, the stratopause descends over some locations by as much as 20 km, as shown in Figure 2.

Figure 1 Typical rocketsonde observations above West Geirinish (57° N, 7° W) before (blue) and at the height of (red) a major stratospheric warming.

Before the onset of the warming, the stratospheric circulation is dominated by a cold and strong westerly polar vortex, which lies over the North Pole, covering most of the Northern Hemisphere outside the tropics (Figure 3). During a so-called major warming, this polar vortex is almost entirely broken down in a matter of days. The stratospheric circulation undergoes a dramatic change. Westerly winds are replaced by easterly winds throughout much of the stratosphere at high latitudes. The occurrence of a major warming can be detected in the stratosphere over the whole globe.

Major warmings do not occur every winter. Typically, six major warming events are observed in a decade, but there is significant variability between different decades. Over the short observational record in the stratosphere, there have been extended periods with no major warmings (1992–98) and periods with major warmings almost every year (the 2000s). So-called minor warmings occur almost every winter. Although

Figure 2 Schematic evolution of temperature at about 60° N during the development of a major midwinter warming. Notice that the height of maximum temperature defining the stratopause descends with time.

Figure 3 Typical fields of geopotential height (a) and temperature (b) for the winter stratosphere of the Northern Hemisphere at 10 hPa, near 30 km, on 1 December 1981. The polar vortex corresponds to low values of geopotential height and temperature. Winds circulate around the polar vortex in a counterclockwise direction on the figure. The Aleutian High is marked by the shaded patch near the dateline at 180° E. Winds circulate around it in a clockwise direction on the figure. Latitude circles are marked at 30° N and 60° N, and the edges of the panels are tangential to the 20° N line of latitude. Units: km for geopotential height; K for temperature.

there are large increases in temperature during such events, the polar vortex is not broken down.

Major warmings do not occur in the stratosphere of the Southern Hemisphere (though an exceptional event, resembling wave-2 major warmings in the Northern Hemisphere, occurred in September 2002). The polar vortex is much stronger than that of the Northern Hemisphere and less readily disrupted. Warmings do, however, occur in spring when the vortex is in the process of weakening during the springtime transition from westerly winds in winter to easterly winds in summer. They are called ‘final warmings,’ because the polar vortex does not recover until the following winter.

SSWs lead to a net poleward and downward transport of stratospheric air. They also bring about a vigorous mixing of air

of polar origin with air of subtropical (or tropical) origin, thereby weakening any preexisting, latitudinal gradients in the concentrations of chemical constituents.

SSWs are generated by the upward propagation of planetary-scale disturbances from the underlying troposphere. The precise nature of the links between stratosphere and troposphere during SSWs has been difficult to establish, because SSWs are highly nonlinear dynamical events.

A Brief History

In the early 1950s, knowledge of the stratosphere was still woefully inadequate. Richard Scherhag, at the newly established Free University of West Berlin, had used radiosondes to construct monthly mean maps of the stratosphere at a height of 22 km. He realized that a new American radiosonde, which remedied some shortcomings with earlier models, would allow reliable measurements of temperature to be made up to a height of 40 km or more. Starting in January 1951, he arranged for these radiosondes to be launched regularly from Tempelhof Airport in Berlin. He witnessed the first ‘explosive warming’ on 27 January 1952; it came as a complete surprise. He noted that temperatures rose to values that were not reached even at the height of summer.

Scherhag set up a group of stratospheric meteorologists at the Free University of Berlin. For decades, by using data from radiosondes and rocketsondes, this group assiduously constructed maps for the Northern Hemisphere of geopotential height and temperature at selected pressure levels in the stratosphere up to 10 hPa. (The paucity of sondes meant that such maps could not be constructed in the Southern Hemisphere.) Thanks to the efforts of this group, the nature, extent, and evolution of SSWs were revealed. Today, the radiosonde network is much improved, and satellites give continuous global coverage of the state of the atmosphere, including the stratosphere. Yet the important discovery of SSWs resulted from a single measurement made in the right circumstances.

Classification and Description of SSW

A typical state of the stratosphere of the Northern Hemisphere during winter was presented in Figure 3. Two vortices are present: the cold polar vortex, which dominates the circulation, and a persistent, but weaker, anticyclone near the dateline, referred to as the Aleutian High. The intensification of the Aleutian High and the accompanying weakening of the polar vortex, almost invariably play a major part in the evolution of SSWs.

The four following kinds of SSW have been identified: major midwinter warmings, minor warmings, Canadian warmings, and final warmings.

Major Midwinter Warmings

Major midwinter warmings occur mostly in December, January, and February. In addition to a warming of the north polar region and the reversal of the normal wintertime temperature gradient (cold pole; warm tropics), they lead to a breakdown of the polar westerly vortex, which is replaced by

an anticyclone (usually the Aleutian High). The World Meteorological Organization classifies warmings as major when the usual westerly winds of the Arctic at 10 hPa are replaced by easterlies as far south as 60° N.

The polar vortex is either displaced entirely from the pole or splits in two. These warmings are therefore often referred to respectively as ‘wave-1’ warmings and ‘wave-2’ warmings because these zonal wave numbers tend to dominate the evolution of the geopotential height field in each case. It can, however, be more useful and instructive to describe the events in terms of how the vortex evolves during the event, namely vortex displacement and vortex splitting events. Some major warmings exhibit a hybrid character, with the polar vortex being displaced asymmetrically from the pole and then split.

Wave-1/vortex displacement type

Figure 4 shows a classical example of a wave-1 type SSW, which occurred in northern winter 1986/87. The Aleutian High (near the dateline) has intensified, displacing the polar vortex and the associated cold air from the pole. Such intensification is often the result of merger between the quasi-stationary Aleutian High and an eastward-traveling anticyclone that forms to the west near 0° E and is then advected eastward around the polar vortex. Temperatures rise sharply in the strengthening jet stream between the polar vortex and the Aleutian High. This temperature rise is the result of adiabatic compression of the air as it descends (by up to about 2 km) on entering the jet stream. The polar vortex is characterized by high values of potential vorticity. It weakens rapidly as air with high values of potential vorticity is drawn away into the anticyclonic circulation (see Figure 5, described later, for an illustration of the process). As the warming subsides, the polar vortex recovers by radiative cooling of the polar air.

Figure 6 shows the accompanying evolution at 10 hPa of zonal-mean winds and temperatures (quantities averaged around latitude circles). A sharp rise in polar temperatures is evident in December, leading to a reversal of the north–south temperature gradient, and accompanied by a rapid deceleration of zonal-mean winds. The winds reverse from westerly to easterly as far south as 60° N, so the event would be classified as ‘major.’

Wave-2/vortex splitting type

The most dramatic major warmings involve a complete split in the polar vortex, followed by a rapid breakdown of one or both of the two cyclonic vortices that result from this split. The growth of the Aleutian High is accompanied by the development of a second anticyclone in the vicinity of the Greenwich Meridian at 0° E. An unusually symmetrical example of a ‘wave-2’ major warming occurred in northern winter 1984/85. Its evolution is illustrated in Figure 7. There are two developing anticyclones: the Aleutian High near 180° E and another (nonclimatological) anticyclone near 0° E. The polar vortex was split in the ‘pincer’ formed by these anticyclones, which then merged over the pole, as shown in Figure 8, bringing warm air over the polar cap. Subsequently, both of the cyclones weakened rapidly as they were stretched out around the strong anticyclone over the pole. Often, vortex splitting events are preceded by a ‘preconditioning’ of the vortex in which it is displaced from the pole and elongated. This

Figure 4 Fields of geopotential height (a) and temperature (b) for the Northern Hemisphere at 10 hPa on 10 December 1987 at the height of a major warming of the wave-1 type. The Aleutian High (gray shading) has moved over the pole; the polar vortex is displaced from the pole and is much weaker than normal. Temperatures over the polar cap are now higher than at lower latitudes, the reverse of normal conditions in the winter stratosphere. Units: km for geopotential height; K for temperature.

preconditioning has a strong signature in the wave number one geopotential height field meaning that separating vortex displacement and vortex splitting events purely on the basis of the amplitudes of the wave number one and two geopotential height field can be difficult. Instead, alternative methods, which focus on examining the two- and three-dimensional structure of the potential vorticity fields have proved a useful complement to traditional methods in classifying and understanding SSWs in recent years.

Minor Warmings

Minor warmings occur every winter in the stratosphere of both hemispheres. They share many of the characteristics of ‘wave-1’ major warming, except that the polar vortex is not broken

Figure 5 This figure illustrates the strong, quasi-horizontal mixing of air that occurs in the stratosphere during an SSW. It was derived by using a high-resolution Lagrangian method in which the movement of many thousands of air parcels was computed. Streamers of air (delineated by blue shading) are being drawn from low latitudes into the Aleutian High, the red area at the top of the figure containing yellow swirls. Air from the polar vortex, shaded yellow, is also being drawn into the Aleutian High where it mixes with the air from low latitudes. Through this loss to the Aleutian High of air that has high values of potential vorticity, the polar vortex weakens during an SSW.

down and the wind reversal from westerly to easterly is less extensive. Major warmings are often preceded by a series of minor warmings, which may serve to weaken the polar vortex steadily after midwinter, making it more susceptible to a complete breakdown.

One particular type of minor warming is the so-called, Canadian warming. These events occur in early winter in the stratosphere of the Northern Hemisphere, typically from mid-November to early December. (They have no counterpart in the Southern Hemisphere.) They show a special kind of structure and evolution, illustrated in Figure 9. The warm Aleutian High is advected eastward in a few days from its normal position over the dateline toward the 90° W line of longitude

over Canada. The polar vortex is displaced from the pole and strongly distorted, but does not break down. Temperature changes are modest compared with major warmings, and affect mainly the middle and lower stratosphere. As the Aleutian High collapses, the vortex regains its usual polar position.

Final Warmings

Springtime final warmings mark the transition in the stratosphere between westerly winds in winter and easterly winds in summer. This transition does not occur smoothly, as it would were it driven purely by radiative heating, but in a sporadic manner owing to dynamical variability of the vortex. A final

Figure 6 Evolution of zonal-mean temperature and zonal-mean wind for the Northern Hemisphere at 10 hPa from November 1987 through April 1988. The rapid rise of zonal-mean temperature in early December is accompanied by a rapid deceleration of zonal-mean wind, which changes direction from westerly to easterly as far south as 60° N. The subsequent polar cooling and midlatitude recovery of westerly winds correspond to the recovery of the polar vortex by radiative cooling after the stratospheric sudden warming.

Figure 7 Fields of geopotential height (a) and temperature (b) for the Northern Hemisphere at 10 hPa on 28 December 1984, during the build up to a major warming of the wave-2 type. The Aleutian High near the dateline (shaded) is accompanied by a second (nonclimatological) anticyclone near longitude 0° E. The polar vortex is in the process of splitting into two cyclones. Units: km for geopotential height; K for temperature.

warming is said to have occurred when the latitudinal temperature gradient finally changes sign at the end of winter and easterly winds remain at middle and high latitudes. **Figure 6** illustrates these changes for a final warming in the Northern Hemisphere near the beginning of April 1988.

Final warmings are the main type of dynamical variability in the stratosphere of the Southern Hemisphere. Their evolution is very similar from year to year, and is illustrated in **Figure 10**. A quasi-stationary anticyclone appears near the dateline, typically in early October. The intense polar vortex weakens from the top of the stratosphere steadily downward, as warm air progressively replaces cold air over the polar cap. This breakdown extends down to the lower stratosphere, where a remnant of the polar vortex remains to intensify again during the following winter.

Figure 8 Fields of geopotential height (a) and temperature (b) for the Northern Hemisphere at 10 hPa on 2 January 1985 at the height of a wave-2 major warming. The two anticyclones shown in **Figure 7** have merged over the pole, and warm air has spread over the polar cap. The two cyclones are weakening rapidly as they are drawn westward around the anticyclone (clockwise on the figure). Units: km for geopotential height; K for temperature.

Recent work has suggested one further interesting contrast between the two hemispheres in the evolution of the final warming in the vertical. In the Southern Hemisphere, the final warming almost always occurs from the top-down with the vortex first breaking down at 1 hPa in November followed by subsequent breakdown at higher pressures with a final breakdown at 50 hPa at the end of December. In the more dynamically active Northern Hemisphere, the final warming can occur with two different distinct vertical structures, a top-down mode similar to that in the Southern Hemisphere and a mode in which the vortex breaks down first in the middle stratosphere (~ 10 hPa). In the top-down mode the vortex breaks down at 1 hPa in late April and at 50 hPa in mid-May. In the middle-first mode the vortex breaks down at 10 hPa in early April and subsequently at 50 hPa in late April; the vortex in the upper

Figure 9 Fields of geopotential height (a) and temperature (b) for the Northern Hemisphere at 10 hPa on 7 December 1981 during a Canadian warming. The Aleutian High (gray shading) has been advected eastward from its usual position near the dateline to 90° W (over Canada). The polar vortex, though displaced from the pole, remains strong. Notice that the temperature changes over the polar cap are much less than those occurring during major warmings, as shown in [Figures 4](#) and [8](#). Units: km for geopotential height; K for temperature.

Figure 10 Fields of geopotential height (a) and temperature (b) for the Southern Hemisphere at 10 hPa on 15 October 2001 during a final warming. A quasi-stationary anticyclone (gray shading) has developed over the dateline and the polar vortex is in the process of weakening. At the level shown, warm air has already replaced cold air over the polar cap. The weakening and breakdown of the polar vortex proceeds in a 'top-down' manner from the upper stratosphere to the lower stratosphere.

stratosphere follows a similar evolution to the top-down mode with a breakdown at 1 hPa in late April.

Theories of SSW

Early Ideas

An early theory was that SSWs were due to solar 'storms.' Scherhag entitled his first paper on the phenomenon "Proof of the Influence of Solar Eruptions on the Weather in the Stratosphere." In this, he tried to link an unexpected, intense SSW to a very strong eruption on the sun. It is now known, however, that the warming he observed began much earlier than the solar event.

By the 1960s, theoretical studies were providing compelling evidence that SSWs originated from the upward propagation of planetary-scale disturbances in the troposphere, visible as a large-scale meandering of the westerly jet stream in the troposphere at midlatitudes. It was shown that the direction and strength of the winds in the stratosphere exert a strong control on the ability of these disturbances to propagate upward. The theory showed that in summer, when winds in the stratosphere are easterly, disturbances cannot propagate out of the troposphere to any great extent. This finding explains why SSWs occur only in winter and not in summer. The theory showed that during winter, when winds in the stratosphere are westerly, the longest, planetary-scale disturbances can propagate from the troposphere right through the stratosphere, but

shorter-scale disturbances, characteristic of weather systems in the troposphere, are confined to lower altitudes. This filtering effect of the westerly winds in the stratosphere explains why the geopotential height and temperature patterns associated with SSWs have characteristically large horizontal scales.

Paralleling this theoretical work, studies based on observational data showed that SSWs are accompanied by an increase in the upward energy flux from the troposphere. Building on this finding, the seminal modeling and theoretical work of Taroh Matsuno in the early 1970s provided compelling evidence for the tropospheric origin of SSWs, and set out a theory of SSWs, which is broadly accepted today.

Matsuno's Theory of SSWs

Matsuno's theory of SSWs was built around a theoretical model of stratospheric dynamics that divides the circulation into zonal-mean (averaged around a latitude circle) and wave components (departures from the zonal mean). He postulated that the mean-flow changes observed during sudden warmings, including the deceleration in zonal-mean wind and the mean temperature rise near the pole (Figure 6), are attributable to the effects of vertically propagating planetary waves forced in the troposphere by large-scale disturbances there. A theoretical finding, the Charney–Drazin nonacceleration theorem, had demonstrated that steady, conservative, linear planetary waves are incapable of inducing such mean-flow changes. Matsuno realized that the nonacceleration theorem would be violated when a transient packet of planetary waves first starts to propagate upward. Calculations showed that at the leading edge of the packet a westward body force would be exerted at midlatitudes on the zonal-mean wind. In addition, a zonal-mean temperature increase would occur at polar latitudes (as well as a zonal-mean temperature decrease at low latitudes). Thus, the mean-flow changes associated with the leading edge of a transient planetary-wave packet are qualitatively similar to those observed during SSWs.

Matsuno gave a convincing demonstration of the validity of these theoretical ideas by using a simplified numerical model to simulate the interaction between a single planetary wave and the zonal-mean flow. Wave amplitudes could be specified at the lower boundary of the model near the tropopause, so that the effects of forced, transient planetary waves could be studied. He found that the interaction between the planetary wave and the mean flow led to an evolution of mean wind and temperature fields, which in some cases was reminiscent of that occurring during SSWs. Figure 11 shows fields from an experiment in which the forcing was a planetary wave with zonal wave number 2 (high–low–high–low around a latitude circle). Westerly winds were replaced by easterly winds after about 20 days of integration, and there was an accompanying rapid temperature increase of over 80 K in the simulated stratosphere. The evolution shown in the figure is reminiscent of that seen during SSWs of the wave-2 type described earlier.

The strong association, demonstrated by Matsuno's numerical simulations, between SSWs and transient wave activity in the troposphere offers an immediate explanation of why SSWs do not occur in the Southern Hemisphere during midwinter. Planetary waves are generated by mountains and by contrasts between the temperatures of land and sea. Because much of the

Figure 11 Results from a numerical simulation of an SSW by Taroh Matsuno using an idealized model. The figure shows polar stereographic plots of the time evolution of temperature (thin curves, marked in degrees Celsius) and height (thick curves, 0.5 km intervals) for the isobaric surface corresponding to a height of about 30 km, near 10 hPa. The contours cover the area north of 30° N. Compare this sequence of plots with the sequence shown for an actual wave-2 major warming by Figures 7 and 8.

Earth's surface in the Southern Hemisphere is oceanic, such waves are weaker than in the Northern Hemisphere. The polar vortex in the Southern Hemisphere is correspondingly stronger and more resilient to any short-term increases in planetary wave activity in the troposphere.

Additional Dynamical Aspects

Since Matsuno's seminal work, numerous SSWs have been studied utilizing global observational data from satellites. These studies have amply confirmed the premise that SSWs are associated with increases in the upward fluxes of planetary wave activity in the stratosphere.

However, two features of Matsuno's numerical experiments must be amended for detailed application to actual SSWs. First, SSWs are highly nonlinear dynamical events. The neglect of wave-wave interactions in Matsuno's simplified model means that certain aspects of stratospheric variability cannot be captured by the model. Secondly, Matsuno's experiments involve planetary wave perturbations to a stratospheric state that is initially zonally symmetric. For actual warmings, the initial asymmetry of the stratospheric state is relevant. As we have already noted, wave-1 warmings often arise when an eastward-traveling anticyclone in the stratosphere merges with the preexisting, quasi-stationary Aleutian High, leading to its intensification and an associated weakening of the polar vortex. Wave-2 warmings tend to develop from an earlier wave-1 minor warming, when the stratospheric polar vortex is already highly elongated and therefore more susceptible to splitting.

An Alternative Hypothesis – Self-Tuned Resonance

An alternative to the broadly accepted Matsuno model of warmings described above is the idea originally proposed by Alan Plumb in 1981 that warmings might occur through the resonant growth of an oscillatory mode of the polar vortex excited by the interaction of the vortex with the underlying topography. Importantly in the Plumb model, the vortex need not be forced precisely at the resonant frequency because nonlinear effects can allow the system to 'self-tune' toward the resonant state. In September 2002, a major, vortex splitting sudden warming was unexpectedly observed in the Southern Hemisphere. This has led to resurgence in interest in the dynamics of sudden warming events and in the self-tuned resonance theory in particular. An interesting hypothesis resulting from this work is the idea that vortex splitting and vortex displacement warmings might have fundamentally different underlying dynamics, in contrast to the Matsuno theory above. Vortex splitting events like the 2002 Southern Hemisphere sudden warming might be best explained as the resonant excitation of the barotropic or external vertical Rossby mode of the vortex.

Dynamical Links with the Troposphere

Although some progress has been made in establishing which features of the tropospheric circulation can produce SSWs, the precise nature of these connections remains somewhat elusive.

Broadly speaking, it appears that the strength of the stratospheric Aleutian High, the growth of which almost invariably plays a part in SSWs, is strongly influenced by the strength of a large-scale climatological feature of the tropospheric circulation, the so-called East Asian Low, located near 140° E in longitude. It is the most intense, persistent cyclonic structure in the troposphere (Figure 12). It is produced largely by the Himalayan mountain range and by land-sea contrasts in winter between the cold Asian continent and the warmer Pacific Ocean. To a first approximation, the Aleutian High can be viewed as part of a downstream Rossby wave train emanating from the East Asian Low.

Some major SSWs of the wave-1 type do appear to be associated with the anomalous intensification of the East Asian Low. It is not the case, however, that there is generally a simple, one-to-one correspondence between an intensification of the Aleutian High and a preceding intensification of the East Asian Low or other tropospheric structure.

Experiments with numerical models have revealed why the expectation of a simple correspondence between transient events in the troposphere and SSWs in the stratosphere, as envisaged in Matsuno's original theoretical scheme, can be frustrated. Experiments with fully nonlinear models show that when planetary wave amplitudes in the troposphere are set to typically observed values and are held steady (i.e., there is no imposed wave transience), the simulated stratosphere exhibits strong internal variability reminiscent of a sequence of minor warmings. In these experiments, the violation of the Charney–Drazin nonacceleration theorem is the result not of transience in wave forcing (as in Matsuno's experiments) but of nonlinearity, which results in transience of both the wave and the mean-flow response. Evidently, if steady waves in the troposphere can cause SSW-like variability in the stratosphere, then a straightforward attribution of an SSW to a transient event in the troposphere cannot always be expected. Nevertheless, it is the case that major SSWs occur when planetary wave amplitudes in the troposphere are anomalously high, even if the exact time sequence of events may be complicated.

Figure 12 Field of geopotential height at 100 hPa near the tropopause on 1 December 1981. The geopotential 'low' in the top right quadrant corresponds to the East Asian Low seen at lower altitudes. Unit: km.

By contrast, attempts to link major warmings of the wave-2 type with the development of specific features in the tropospheric circulation have been more successful. The dramatic split in the polar vortex, which occurs during these events, can often be traced right down into the troposphere, where the East Asian Low is partnered by the appearance of another cyclonic circulation over North America near 90° W (Figure 13) – hence the growth of a strong wave-2 pattern in the troposphere.

Factors Affecting the Occurrence of SSWs on Interannual and Longer Timescales

Different winters show substantial differences in the frequency and nature of SSWs. While much of this variability is likely to be random in nature, the likelihood of SSW occurrence in any particular winter is thought to be influenced by several different processes in the Earth system.

1. Variability in the large-scale structure of the tropospheric circulation;
2. Variability in the tropical stratosphere; and
3. Variability of external forcings.
 - a. A major source of tropospheric variability is the El Niño Southern Oscillation phenomenon (ENSO). Studies with general circulation models have shown that the occurrence of a major SSW is enhanced during both the warm and cold phase of ENSO. This is particularly interesting since the mean state of the stratosphere is warmer/colder during El Niño/La Niña, yet the frequency of SSW is, in both cases, much higher than for neutral conditions in the east Pacific. The mechanism for this important influence of ENSO is still poorly understood, and is the subject of much ongoing research.
 - b. The other dominant source of variability in the tropical stratosphere is the quasi-biennial oscillation (QBO), which involves the quasi-periodic reversal of zonal winds from westerly to easterly and back again. Theory shows that the zonal-wind structure in the stratosphere

affects the propagation of planetary waves from the troposphere. The standard explanation for the relationship between the QBO and changes in the polar vortex is that when the QBO is in its westerly phase throughout the tropical lower stratosphere, the waves are refracted away from polar regions toward the tropics. The stratospheric polar vortex should therefore be cold and strong. When, on the other hand, the QBO is in its easterly phase, the waves are more confined to middle and polar latitudes. The polar vortex should be warmer and weaker and therefore more susceptible to breakdown by SSWs. Recent modeling work has, however, begun to question these ideas and, as in the case of ENSO, further experimentation is needed to fully understand the relationship between the QBO and the frequency of SSWs.

- c. Finally, there are many different external climate forcings, both natural and anthropogenic, that may influence the frequency of SSWs over coming decades. The most persistent of these is the forcing of the stratospheric state by the continued emission of greenhouse gases. Most modeling studies, which examine the number of SSWs in climates with significantly enhanced levels of carbon dioxide suggest that a small increase in the frequency of SSWs is likely to be observed by the end of the twenty-first century (assuming greenhouse gases continue to increase in coming decades). Two important caveats to this broad conclusion, however, are that there are significant differences among climate models in predictions of future SSW frequency, and that the magnitude of any change in SSW frequency is likely to be small compared to decadal variability in SSW occurrence. The extent to which changes in the structure and strength of the polar vortex or changes to the generation of planetary wave anomalies in the troposphere are implicated in the change in SSW remains the topic of current research.

Other external forcings, which might influence the frequency of SSWs predominantly consist of processes, which perturb the stratospheric radiative balance. These include changes in solar output, the decline and recovery of stratospheric ozone, changes to the stratospheric aerosol distribution either through volcanic eruptions or anthropogenic geo-engineering and changes to stratospheric water vapor. Since the study of SSWs as climate phenomenon is relatively recent and since the observational record is relatively short, there has been very limited work, to date, on the influence of these processes on SSW frequency.

It is certainly also important to note that because of the short observational record in the stratosphere and the fact that models have only recently begun to be able to simulate SSWs well, understanding and discovering connections between the SSW frequency and other parts of the climate system is at an early stage. This is an area of research that is likely to expand in future years.

Effects of Sudden Warmings

On the Distribution of Trace Constituents

An SSW irreversibly alters the distribution of trace constituents in the stratosphere. Air is transported over large distances in the

Figure 13 Field of geopotential height at 100 hPa on 28 December 1984. Note the correspondence between this field and that shown in Figure 7. Unit: km.

north–south direction and irreversibly mixed at midlatitudes. In addition, there is an enhancement of the overturning, meridional circulation, consisting of systematic ascent of air at low latitudes and systematic descent of air at high latitudes.

Figure 5 illustrates the large-scale, quasi-horizontal mixing that occurs during an SSW. As the Aleutian High (or any other anticyclone) intensifies, it entrains in air from low latitudes, sometimes from deep within the tropics. Air is also peeled off the polar vortex into the anticyclone, where it is wound into ever narrowing spirals along with the low-latitude air. Any preexisting, latitudinal gradients in chemical concentrations are reduced by this anticyclonic mixing. Chemical reactions can also occur, since previously well-separated reactive species are brought into chemical contact. The breakup of the polar vortex during a major SSW, or during a final warming, leads to the greatest mixing of polar and low-latitude air, bringing, for instance, ozone-poor air from the polar vortex to midlatitudes.

On the Weather

SSWs are the premier mode of coupling between the stratosphere and troposphere, representing both:

- An influence of the troposphere on the stratosphere through the upward propagation and breaking of tropospheric planetary waves, and
- An influence of the resulting changes to the stratospheric mean state on the troposphere on intraseasonal timescales.

In describing stratosphere–troposphere coupling, SSWs can be thought of playing a role analogous to that of ENSO in describing ocean–atmosphere coupling in the tropical Pacific. A key aspect of this coupling is that the circulation anomalies related to SSWs in the lower stratosphere persist for long time (up to 60 days) potentially providing a source of memory for extended-range and seasonal weather forecasts.

The typical response of the tropospheric circulation to an SSW event is often described as a shift of the Northern Annular Mode toward its negative phase. In simpler and more intuitive terms, this means the southward migration and weakening of

the extratropical, eddy driven jet stream. The resulting changes to surface temperature include cold anomalies over North America and Western Europe and warm anomalies over Newfoundland, Greenland, and Southern Europe.

Although this is the widely accepted view of the influence of stratospheric anomalies, several other factors must also be considered. First, some studies show that the influence of SSW events is more consistently as described above in the Atlantic basin than in the Pacific basin. Second, SSWs are also thought to bring about changes in the breaking of baroclinic waves in the troposphere, leading to change in the position and structure of the synoptic weather systems, which dominate day-to-day variations in weather at extratropical latitudes. Finally, experiments which examine if better predictions of the stratospheric state might improve tropospheric weather forecasts suggest that the quantitative size of any improvement to predictability is small but significant.

Synopsis

The transport circulation is forced by upward propagating tropospheric waves that break in the stratosphere and mesosphere, depositing energy and momentum. This drives a global-scale circulation with slow ascent in the tropics balanced by poleward and downward motion in the middle and high latitudes. Observations of long-lived trace gases have elucidated the details of stratospheric transport processes. Transport plays a central role in stratospheric composition through control of the distribution of long-lived gases such as N_2O , CH_4 , and chlorofluorocarbons. Their distributions impact stratospheric ozone and climate.

Introduction

The Physical Basis for the Transport Circulation

The stratospheric meridional circulation, often referred to as the Brewer–Dobson Circulation (BDC), was deduced by Brewer and Dobson from observations of the distributions of water vapor (H_2O) and ozone (O_3). Air enters the stratosphere through the tropical tropopause where it ascends slowly, moving gradually poleward and downward. Above the stratosphere, the mesospheric circulation moves air from the summer to the winter pole. Air in the descending branch of the BDC exits the stratosphere at the extratropical tropopause

and affects tropospheric composition. Figure 1 shows a schematic of the middle atmosphere circulation.

On seasonal and longer timescales, the mean stratospheric circulation can be described in the latitude–height plane where averages are taken around latitude circles ('zonally averaged'). Transport in the middle and high latitudes has a strong seasonal cycle with large interhemispheric differences. The equations of motions governing the zonally averaged circulation can be represented using the Transformed Eulerian Mean (TEM) framework. Because the TEM description formulates complex wave-mean flow interactions in the stratosphere in terms of a single zonal wave force acting on the zonal mean

Figure 1 Schematic of transport circulation in the middle atmosphere. Transport by the Brewer–Dobson circulation (BDC) is shown by blue arrows. In the lower stratosphere, the BDC transports air from the tropics into both hemispheres, then downward through the tropopause. In the middle and upper stratosphere, the BDC has a strong poleward, downward circulation in the winter hemisphere where there is planetary wave (PW) breaking. In the summer hemisphere the upper stratospheric circulation is poleward and upward. The pole-to-pole transport in the mesosphere is shown by the yellow arrow. Gravity waves (GWs) are the major source of wave energy in the mesosphere. The year-round source of tropospheric wave energy propagating into the stratosphere is depicted by red arrows. Regions with restricted two-way transport ('mixing barriers') are indicated by vertical dotted lines. The dashed thick blue line above the troposphere is the tropopause.

flow, it provides the most useful framework for describing mean constituent transport in the extratropics (regions poleward of 30°), where planetary-scale Rossby waves provide the dominant wave forcing. The circulation can also be formulated using isentropic (constant entropy) coordinates. Isentropic surfaces, also known as potential temperature surfaces, are the quasi-horizontal layers along which long-lived stratospheric constituents are adiabatically advected.

Synoptic-scale tropospheric disturbances occur throughout the year creating waves that deposit energy and momentum in the extratropical lower stratosphere, driving the lower branch of the equator-to-pole mean circulation in each hemisphere. In the middle and upper stratosphere, the wintertime stratospheric transport is dominated by large-scale Rossby planetary waves (PWs) that are forced by topography or diabatic heating patterns and propagate upward from the troposphere. When these waves break, they mix air along quasi-horizontal isentropic (potential temperature) surfaces. The region of wave breaking between the tropics and high latitudes is known as the 'surf zone.' Waves tend to break at critical surfaces where the zonal wind is the same as the zonal phase speed of the wave. The large-scale Rossby waves are quasi-stationary (i.e., have zero phase speed) and cannot propagate through the zero wind line. In summer, stratospheric winds in the extratropics shift from Westerly to Easterly, and the PWs are no longer able to propagate into the stratosphere. Without energy and momentum from breaking waves, the summer circulation is weak. Mixing processes are slow and temperatures are near radiative equilibrium.

Inertia-gravity waves, with a broad distribution of horizontal phase speeds, propagate upward through the stratosphere year-round regardless of wind direction, depositing momentum in the upper stratosphere and mesosphere. The wave energy drives the mesosphere far from radiative equilibrium, leading to a strong circulation equatorward from the summer pole and poleward in the winter hemisphere. Diabatic cooling at the winter pole leads to strong downward transport of mesospheric air deep into the stratosphere.

Diabatic heating increases with altitude in the stratosphere primarily due to the absorption of solar UV radiation by O_3 . In spite of this thermal forcing, the stratospheric circulation is predominantly driven by the deposition of momentum from waves. Rossby wave breaking in the winter hemisphere not only mixes constituents in the midlatitude surf zone but also leads to a net poleward and downward transport. As mass sinks at high latitudes in the descending branch of the BDC, the air adiabatically warms and keeps polar temperatures above radiative equilibrium. The circulation driven by the net heating is called the diabatic circulation and it represents approximately the same global-scale meridional circulation described by the TEM framework. This wave-driven circulation is also referred to as the 'extratropical pump' because midlatitude wave driving effectively draws air poleward and downward while the tropics respond with rising motions and adiabatic cooling.

The Impact of the Transport Circulation on Trace Gases

The BDC, depicted two-dimensionally (2D) in [Figure 1](#), represents the slow net meridional (horizontal) and vertical motions of mass in the middle atmosphere. The mean

timescale for an air parcel to travel through the middle atmosphere may be up to ~ 6 years. Trace gases enter the stratosphere through the tropical tropopause. As the tropical air slowly ascends, it is exposed to increasingly higher levels of UV radiation and increasing concentrations of reactive species (i.e., radicals). The longer an air parcel has been in the stratosphere, the greater the likelihood it has traveled to high altitudes where it experienced photochemical loss. For many long-lived species, such as the tropospheric source gases, nitrous oxide (N_2O), methane (CH_4), and chlorofluorocarbons (CFCs), photochemical losses become important in the middle stratosphere (~ 30 hPa) and above, primarily in the tropics. Breaking planetary-scale waves in the winter hemisphere drive the 'extratropical pump' which transports tropical air poleward and downward into the photochemically cooler environment of the middle and high latitudes. The integrated effects of transport and exposure to reactive chemical environments control the large-scale mean distributions of long-lived trace gases as well as their lifetimes.

[Figure 2](#) shows the zonal mean structure of two long-lived trace gases, N_2O and CH_4 . The lines of constant mixing ratio (isopleths) are lifted upward in the tropics by the ascending branch and are pushed downward in the middle and high latitudes by the descending branch of the BDC. Tracer isopleths in the middle latitudes of the winter or spring hemisphere are flattened as a result of rapid mixing by breaking PWs, creating a 'surf zone.' The balance between horizontal mixing (flattening) and the diabatic circulation (steepening) produces the observed tracer slope.

Although N_2O and CH_4 have different tropospheric sources and different photochemical loss processes – including differences in the altitudes and latitudes where losses occur – their stratospheric distributions shown in [Figure 2](#) are quite similar. These observations provide compelling evidence that their features are controlled by transport and hence dynamical processes. This is the case for all long-lived trace gases, where long-lived means that the timescales for chemical production or loss are much longer than the timescales for transport. When two trace gases are controlled by transport they show a compact correlation. This has been demonstrated by numerous studies of stratospheric trace gas, many using observations from aircraft campaigns. The compact correlation between N_2O and CH_4 in the lower stratosphere is illustrated in [Figure 3](#). The compactness arises because horizontal transport occurs rapidly compared to vertical transport by the circulation. Ozone has rapid production and loss processes in the middle stratosphere but is long-lived in the lower stratosphere. It shows a compact correlation with species such as N_2O and CH_4 in the lower stratosphere.

The combined effects of the slow, mean-meridional circulation of the stratosphere and rapid isentropic mixing in the midlatitude surf zone result in three relatively separate regions in the winter hemisphere. The left panel of [Figure 4](#) shows the zonal mean distribution of Microwave Limb Sounder (MLS) N_2O data from a day in northern winter. The midlatitude surf zone is easily identified by the flattened isopleths from 450 to 1000 K (approximately 7–70 hPa) in between the tropical and polar regions. The right panel of [Figure 4](#) shows an area-weighted probability distribution function (PDF) of MLS N_2O data from tropical to polar latitudes on a single potential

Figure 2 Zonal mean climatologies 80°S – 80°N in September and October N_2O and CH_4 (ppb) derived from SCISAT-1 Atmospheric Chemistry Experiment (ACE) observations, 2004–09. Figure 3 The compact correlation of ACE N_2O and CH_4 in September and October in the lower stratosphere and tropical upper troposphere, 200–50 hPa. The compactness is a consequence of horizontal mixing occurring on timescales shorter than vertical transport by the BDC.

temperature surface. The PDF shape reveals well-mixed regions along with a lack of mixing between them. This PDF indicates that tropical air ($\text{N}_2\text{O} > 220$ ppb) is well mixed, i.e., has a fairly narrow distribution, but is isolated from the effects of midlatitude mixing. It is not completely isolated as some mixing ratios are observed that are intermediate between tropical and midlatitude values, e.g., 210 ppb. The midlatitudes are also well mixed (approximately 120–180 ppb), but quite isolated from the lower mixing ratios found in the polar vortex (10–20 ppb). The minimum in between the midlatitude and vortex peaks is deep and wide, indicating extremely weak mixing between these regions. These minima are referred to as

the subtropical and polar vortex transport barriers. High N_2O mixing ratios in the ascending BDC are associated with recent arrival of tropospheric air in the stratosphere having little photochemical loss, while low N_2O at high latitudes found in the descending branch of the BDC is photochemically aged air. It has spent years in the stratosphere with greater exposure to photochemical loss.

The high latitude gradient develops when the vortex forms, as polar air diabatically (radiatively) cools and descends in the fall. Wave-driven radiative cooling strengthens the poleward downward circulation of the BDC. (This also increases ascent rates in the tropics.) The effect of waves on the downward circulation is

Figure 4 Left: Zonal mean N₂O observed by Aura MLS on 16 January 2007 on potential temperature (isentropic) surfaces. Approximate pressure levels are given on the right side of the plot. The broad, flat region in the midlatitudes is the well-mixed surf zone. Steep gradients near 25° and 70° reflect the isolation of the tropics and the high latitudes (vortex). The dashed line at 700 K (~18 hPa) corresponds to the data used in the probability distribution function (PDF) calculation on the right. Right: Area-weighted PDF of the N₂O observations on the 700 K surface, averaged over 10 days in January. The PDF maxima indicate three well-mixed regions: the polar vortex (10–20 ppb), the midlatitude surf zone (120–170 ppb), and the tropics (>220 ppb). The minima between the peaks indicate weak mixing between the regions.

less inside the vortex, resulting in smaller descent rates there than at the vortex edge. Because waves do not usually penetrate the vortex, vortex air becomes isolated and long-lived trace gases such as N₂O have low values in the vortex relative to the midlatitudes. The net result of these processes, mid- and high-latitude descent and isentropic mixing restricted to the midlatitudes, is to create a steep tracer gradient at the vortex edge. When the sun returns to the winter hemisphere in spring, strong wave activity disturbs the vortex leading to its eventual breakdown and mixing with midlatitude air. With the vortex gone, so are the steep trace gas gradients between mid- and high latitudes. Unlike the vortex edge, the subtropical edge of the surf zone exists year-round. In winter and spring, breaking midlatitude waves unable to penetrate the tropics lead to a region of weak horizontal mixing in the subtropics, similar to the situation at the vortex edge. The subtropical gradient persists in summer and the fall, but it is less steep because it no longer sharpened by erosion. When midlatitude wave activity is at a minimum, a PDF of the summer hemisphere would show only the midlatitude and tropical peaks with a shallow minimum between them. The strength of each hemisphere's transport circulation varies due to seasonal variations in wave driving, which leads to seasonal variations in trace gas distributions.

The strength of large-scale tropospheric waves propagating into the stratosphere can have significant interannual variations. The interaction of tropical Kelvin and gravity waves forces a downward propagating oscillation in the direction and speed of winds in the equatorial lower and middle stratosphere. The mean period of the oscillation, known as the quasi-biennial oscillation (QBO), is about 26 months. The QBO interacts with extratropical Rossby waves in a way that depends on the phase of the QBO (i.e., Easterly or Westerly). These phase-dependent interactions impact the degree of isolation of the tropics and of the polar vortex, leading to interannual variations in lower and midlatitude stratospheric composition.

Timescales for Transport in the Stratosphere

Mean age is a particularly useful quantity for understanding transport because it is a measure of the integrated effects of circulation and mixing. Stratospheric 'transit time' is the time required for an infinitesimally small fluid element to travel from its stratospheric entry point at the tropical tropopause to any given point in the stratosphere. Due to mixing and seasonal variations in the strength of the circulation, there are many possible transport pathways to a given point, thus the transit time is actually a distribution or 'spectrum' of times. An air parcel may be considered as an observable quantity composed of a large number of fluid elements, each with its own transport pathway and time. The mean age of a parcel is the average of the transit times of all the fluid elements comprising the parcel. The older the mean age of air, the more likely the air has traveled to high altitudes where it would be exposed higher UV levels and fast photochemistry. Observations of certain very long-lived trace gases, with well-measured growth rates in the troposphere, can be used to deduce transport timescales (mean age) in the stratosphere.

Stratospheric Transport Derived from Observations

Over the past 30 years, satellite datasets, along with observations from aircraft and balloon campaigns, have clarified our understanding of the transport circulation, leading to a detailed understanding of many transport processes. For example, instruments on the NASA Upper Atmosphere Research Satellite (UARS, 1991–2005), the NASA Aura satellite (2004–ongoing), and the Canadian SCISAT-1 (2003–ongoing) have provided multiyear datasets with near global coverage of long-lived trace gases including CH₄, N₂O, H₂O, HF, HCl, CFCl₃ ('CFC-11'), CF₂Cl₂ ('CFC-12'), and O₃. In some cases the instruments also

measure shorter-lived species such as NO_2 , HNO_3 , ClO , and ClNO_3 , whose abundances affect O_3 . Multiyear satellite datasets provide climatological information on stratospheric transport processes and their interannual variability. *In situ* instruments on aircraft and balloon platforms measure many of the same species observed by satellite instruments but at much higher spatial resolution, although their spatial and temporal coverage is limited. Aircraft data with spatial resolution of hundreds of meters have revealed the small scale of filamentation processes occurring at the edge of the polar vortex.

Circulation and Mixing: Age of Air

The extremely long-lived species carbon dioxide (CO_2) and sulfur hexafluoride (SF_6) have surface sources with well-measured growth rates that can be used to calculate the mean age of air in the stratosphere. Empirically, CO_2 mixing ratios and their seasonal cycle observed at the tropical tropopause, i.e., the stratospheric entry point, can be approximated by the average of surface CO_2 measurements at two tropical stations, Samoa (14°S) and Mauna Loa (19°N), delayed by 2 months. Because of the paucity of tropical tropopause measurements, the time series of CO_2 from these stations is used as a convenient proxy for the CO_2 mixing ratio at its entry point to the stratosphere. These stations have measured CO_2 for many decades, allowing growth rates to be accurately calculated. The growth rates allow CO_2 measurements in the stratosphere to be interpreted as a 'clock,' where the elapsed time between stratospheric entry and a particular point in the stratosphere can be determined by when that mixing ratio was observed at the entry point. Figure 5 illustrates how balloon-borne CO_2 measurements made over a period of more than two decades can be compared to the proxy time series at the stratospheric entry point to determine mean age at a point in the middle stratosphere. Notice that both lines have same slope, which is equal to the growth rate of surface CO_2 . The horizontal offset

between the two lines (Δx) is the mean transit time. (Due to the contribution of the oxidation of CH_4 to CO_2 , a correction of ~ 0.5 years must be applied to the mean age derived from this method.) This data analysis shows that the mean transit time to the midlatitude middle stratosphere has consistently been ~ 5.0 years for more than two decades.

Figure 6 shows mean age derived from CO_2 and SF_6 measurements from a wide range of latitudes and altitudes made over a period of more than 30 years. These data represent a wealth of knowledge about the combined effects of circulation and mixing in the midlatitudes and tropics. Mean age in the tropics is low, reflecting the recent entry of air in the stratosphere. Age increases with latitude because of increasing contributions from air descending from higher altitudes in the stratosphere (see Figure 1). Mean ages in the polar regions have large seasonal variability, reflecting the seasonal variations in the descending branch of the BDC.

Tropical Ascent and Subtropical Mixing

Aircraft campaigns in the late 1980s and the early 1990s, flying from the subtropics to the tropics in both hemispheres observed sharp meridional gradients in long-lived trace gases, e.g., N_2O , O_3 , and NO_y (a long-lived quantity equal to the sum of all reactive nitrogen species). This revealed the isolation of tropical air from the midlatitudes, providing evidence that the strong mixing in the surf zone did not penetrate the tropics. The global-scale picture of tropical isolation was uncovered using satellite measurements of H_2O , CH_4 , and temperature with the discovery of the 'water vapor tape recorder.' Water vapor becomes 'freeze dried' as it ascends through the cold tropical tropopause – a very cold region, typically 190–195 K. The extratropical pump (wave driving) that controls the strength of the BDC is strongest in northern winter and weakest in northern summer. This causes tropical tropopause temperatures to be lowest in winter and highest in summer. The seasonal cycle in tropopause temperatures modulates the

Figure 5 Proxy time series of CO_2 at the tropical tropopause (gray) and midlatitude CO_2 observations from ~ 45 to 50°N , 20–25 km (50–25 hPa) (symbols). The lines represent the best fit to the points. The temporal offset between the two lines gives the mean stratospheric transit time to 45 – 50°N , 20–25 km. From Andrews, A.E., et al., 2001. saturation vapor pressure of water entering the stratosphere. As air slowly ascends in the tropics, the temperature-modulated H₂O mixing ratios produce an upward propagating cycle, shown in Figure 7. The water maxima (orange) are mixing

ratios that passed through the tropopause when it was relatively warm (summer), while the minima (blue/green) are the low mixing ratios that ascended through a colder tropopause (winter). The maxima (or minima) appearing at ~26 km

originated at the tropopause 1 year earlier. The vertical velocity is calculated from the upward motion of the cycles' minimum or maximum (bottom of Figure 7). Vertical diffusion is negligible and does not affect the location of the extrema. The amplitude of the cycle diminishes very slowly with height, indicating weak mixing of midlatitude air into the tropics. The tape recorder analysis provides empirical evidence for two key transport quantities: ascent rate and subtropical mixing strength as a function of height. These transport processes together effectively control mean age in the lower stratosphere.

High Latitude Descent and Isolation

The high latitude edge of the surf zone provides a similar study of the balance between rapid mixing in the midlatitude surf zone and the descending branch of the circulation. As in the subtropics, this balance results in steep gradients in long-lived trace gases at the boundary between the regions. Lower stratospheric aircraft missions in the late 1980s found very steep gradients in N_2O and other long-lived species at the edge of the Antarctic and Arctic vortices in winter, confirming the isolation of vortex air from the surf zone. Large O_3 loss occurs each austral spring inside the Antarctic vortex because of the meteorological conditions there. The first condition, low temperature, is required for the formation of polar stratospheric clouds (PSCs), which convert HCl and ClONO_2 into reactive forms of Cl while denitrifying the air. And the second condition, isolation, is necessary in order to maintain the highly perturbed chemistry required for PSC-driven O_3 loss. If there were strong mixing with midlatitude air, vortex air would be warmer, PSCs would evaporate, and HNO_3 would be resupplied to the vortex where it would consume reactive Cl .

The tape recorder shows that tropical air is isolated in all seasons, but the isolation of polar vortex air is a seasonal phenomenon. The vortex forms in the fall and breaks down in spring. The Antarctic vortex generally lasts until late spring (November) while the Arctic vortex, subject to far more wave disturbances than its Southern Hemisphere counterpart, has a final breakdown in early spring, March or April, and may experience a midwinter 'sudden stratospheric warming' (SSW). In an SSW, the existing vortex may be pushed off the pole to lower latitudes and destroyed by mixing in the surf zone. If a new vortex forms, which is likely if the SSW occurs before March, its composition will be that of the midlatitude air that replaced it. The degree of vortex isolation therefore has a major effect on Arctic stratospheric composition. The Antarctic vortex composition has less interannual dynamical variability due to weak wave driving during winter and early spring. The Arctic vortex composition shows significant interannual variability due to variations in wave driving, which affect descent as well as the permeability of the vortex edge. Both processes transport high O_3 into the polar region. Large interannual variations in the permeability of the Arctic vortex edge and circulation strength (i.e., descent) make the precise calculation of O_3 loss due to heterogeneous reactions (PSCs) difficult because the amount of O_3 transported into the vortex each winter is variable and difficult to quantify.

Figure 8 shows examples of interannual variability in the composition inside the Arctic vortex using ozone measured by the Aura MLS instrument. These data are from the 700 K

Figure 8 Left panels: Aura MLS O_3 (in ppb) on the 700 K surface (~ 15 hPa) in early winter (December 28) of 2004 and 2005. Right panels: Aura MLS O_3 on the same surface in late winter. Ozone loss from gas phase and heterogeneous chemical reactions is negligible at these levels. The large difference in March O_3 in these 2 years is due to transport.

(15–18 hPa) surface, which has little or no PSC activity. The observations shown in the left panels are from early winter of two consecutive years. The Arctic winter of 2004–05 (top panels) was very cold winter with little wave activity, while 2005–06 (bottom panels) was a relatively warm winter with frequent wave activity including a midwinter SSW. In early winter, both years show similar areas of low O_3 inside an intact, isolated vortex. Note that O_3 gradients at the vortex edge in December 2005 are steeper than 2004, a less-disturbed year. This is an example of how wave activity acts to erode and sharpen the vortex edge. The panels on the right show O_3 in early March. In March 2005, the vortex had been relatively cold and undisturbed by waves all winter while the vortex in March 2006 had recently reformed after an SSW. Ozone in March 2006 is more than 1 ppm (1000 ppb) higher than the previous year due to strong wave activity, which brought high O_3 air from the midlatitudes to the pole during winter. These differences reflect differences in advection and mixing (transport) rather than the effects of heterogeneous chemical ozone loss by PSCs.

Descent through the Extratropical Tropopause

Air leaves the stratosphere through the extratropical tropopause, approximately 30 – 90° in each hemisphere, as shown in Figure 1. The net transport by the BDC at the tropopause is downward and very little extratropical upper tropospheric air enters the stratosphere through upward motion. The tropopause acts as a transport barrier and this is confirmed through observed trace gradients at the tropopause. Carbon dioxide

(CO₂) has a ~4-ppm amplitude seasonal cycle in the Northern Hemisphere upper troposphere (UT) due to seasonal variations of sources and sinks. The amplitude of the CO₂ seasonal cycle just above the northern midlatitude tropopause is ~2 ppm and is phase lagged by several months relative to the UT cycle. If rapid mixing across the tropopause occurred, the seasonal cycles above and below the tropopause would be the same.

Improving Our Understanding of the Transport Circulation: Observations and Models

How Observations Affect Model Development and the Ability to Predict

Observational analyses such as the ones presented in the previous section provide a detailed understanding of key transport processes. The state of our understanding of the transport circulation is represented in three-dimensional (3D) chemistry climate models (CCMs). These models physically represent the chemical, dynamical, and radiative processes that control atmospheric composition. CCMs are used to predict how future changes in surface emissions of CFCs and greenhouse gasses (GHGs) may affect stratospheric O₃. In the late 1990s, several groups compared 2D (zonal mean) and 3D models against stratospheric observations in order to evaluate the realism of the models' representations of transport. Comparisons were made to mean ages derived from CO₂ and SF₆, N₂O vertical and horizontal gradients, and upward propagation of the tropical water tape recorder signal. The results revealed significant shortcomings in transport in most models, in particular, fast circulation and excessive subtropical mixing. Poor transport impacts the lifetimes of ozone-depleting substances (ODSs) in these models, which in turn affects

how quickly stratospheric O₃ is predicted to recover as the emissions of CFCs decrease.

Model evaluations using observations have led to more realistic model transport. In the past two decades, increases in computer speed and decreases in the cost of data storage have made it possible to produce simulations with higher spatial resolution that include processes that were previously parameterized or neglected (e.g., coupling between dynamics and chemistry, tropospheric chemistry). Although these computational improvements are necessary for longer and more complex simulations, new simulations would not advance our understanding or improve our ability to explain and predict if there were not observations to guide model development. Recently, a comprehensive effort was undertaken to assess the radiation, dynamics, chemistry, and transport in CCMs by using observationally derived process evaluation. The transport evaluation identified several key transport processes in the stratosphere that had to be well represented in models, including tropical ascent rates and the degree of mixing across transport barriers in the subtropics and high latitudes. Mean age is a function of both circulation and mixing strength, and is thus a useful model transport diagnostic. Figure 9 provides an example of how well recent CCMs simulate mean age in the lower stratosphere (blue lines) compared to a group of 2D and 3D models from the 1990s (yellow shading). Overall, present-day models have significantly more realistic transport compared to the older models.

The Importance of the Transport Circulation to Short-Lived Species (e.g., O₃)

Although ozone in the middle and upper stratosphere is controlled by the balance between photochemical production

Figure 9 Comparison of observationally derived lower stratospheric mean age with models' simulations (~50 hPa). The range of model mean ages from 11 two-dimensional (zonal mean) and 7 three-dimensional models in the late 1990s is shown by the yellow shading. Blue solid and dashed lines show 15 CCMs participating in a model intercomparison in 2009. Observations and their 2 σ uncertainties are shown by the black diamonds.

and loss, the transport circulation plays an important role in the ozone distribution because it controls the distribution of many of the species involved in ozone loss processes. Radical species NO_2 and Cl play important roles in the catalytic loss cycles controlling O_3 in the middle and upper stratosphere. Their abundances depend on abundances of the reservoir ‘families’ they belong to, NO_y , and Cl_y . ‘ NO_y ’ is the sum of all reactive nitrogen species, mostly NO , NO_2 , HNO_3 , ClNO_3 , and N_2O_5 . ‘ Cl_y ’ is the sum of reactive chlorine species, primarily HCl , ClNO_3 , ClO , plus other minor species. The species within the family are in rapid photochemical equilibrium with each other, but their sum changes very slowly and is controlled by transport. If a model’s circulation is too fast, its mean age will be too young and its trace gases will have had less photochemical exposure; simulated NO_y would be lower than observed, assuming there are no errors in the chemical mechanism. Less NO_y means less NO_2 , which reduces O_3 loss. In the lower stratosphere, Cl_y affects O_3 through heterogeneous chemical loss inside the polar vortex during winter. Cl_y is created when CFCs are transported to the middle and upper stratosphere where they are photolyzed, releasing Cl . Thus Cl_y in the lower stratosphere depends on the transport circulation (i.e., the model’s ability to get CFCs up to appropriate altitudes). Models with young mean age at high latitudes are likely to have too little Cl_y , which reduces the amount of O_3 lost by PSC processes. The accurate simulation of stratospheric composition therefore depends not only on chemistry but also on the correct simulation of the transport circulation.

Understanding the Transport Circulation: Why It Matters?

Understanding the atmosphere’s present-day transport circulation is necessary in order to understand how changes in emissions of anthropogenic GHGs and ODSs will affect the ozone layer and the radiative balance of the atmosphere in the future (i.e., the climate response). Observations, such as vertical or horizontal profiles of stratospheric trace gases and their seasonal variations, reveal underlying physical processes occurring in the atmosphere. The empirical determination of transport processes based on observations provides constraints for model behavior, leading to improvements in the model’s

physical basis. If a model has a realistic representation of physical processes involved in the transport circulation, its response to changes in emissions will also be physically based, increasing the credibility of its composition and climate projections. Currently, some CCMs are able to realistically represent many essential chemical and transport processes in the stratosphere. Continued use of observations to understand stratospheric chemistry and transport processes will lead to greater realism in model simulations and greater confidence in their predictions of future circulation and composition.

This article is a revision of the previous edition article by W J Randel, volume 3, pp 1358–1365, © 2003, Elsevier Ltd.

Synopsis

The term ‘middle atmosphere’ refers to the height region of approximately 10–90 km and is used to characterize the atmospheric region between the troposphere and the thermosphere. The stratosphere and mesosphere form the largest part of the middle atmosphere. This article describes slowly varying climatological features of temperature, zonal wind, and some other derived quantities. The Northern and Southern extra-tropical middle atmosphere will be contrasted in its seasonal behavior, highlighting similarities and differences during winter. The third region covered is the tropical middle atmosphere and the intra-seasonal and interannual variability determining its structure, for example, the quasi-biennial oscillation.

Introduction

The term ‘middle atmosphere’ refers to the height region of approximately 10–90 km and is used to characterize the atmospheric region between the troposphere and the thermosphere. The troposphere is dominated by weather systems and convection, and is generally well mixed. In the thermosphere, ionization and molecular diffusion become important physical processes and govern the behavior of the layer. The stratosphere and mesosphere form the largest part of the middle atmosphere and are the focus here.

This article will describe slowly varying climatological features of temperature, zonal wind (west–east wind, positive when eastward), and some other derived quantities. Much of the discussion will be using latitude–height (or pressure) cross sections of zonally averaged quantities (averaged over all longitudes at a particular latitude and height), because scaling relations in the middle atmosphere are such that the zonal wind is generally larger than the meridional wind (south–north wind, positive when northward). Note that the mean zonal flow is interconnected to the meridional (south–north) mean temperature gradient.

Notwithstanding the possibility of describing the structure of the middle atmosphere in zonal mean terms (two dimensional in space), deviations from the zonal mean are of particular importance during the winter in high latitudes. Planetary waves shape the structure of the stratospheric flow, and wave amplification and breaking waves can lead to rapid changes in the wintertime circulation (wave mean-flow interactions). Even though this behavior can be summarized in a zonal mean framework, in which large-scale temperatures, winds, and forcing mechanisms are linked, the details of this interactions (and their regional relevance) require a full three-dimensional assessment that goes beyond this contribution.

Most of this article will focus on describing zonal mean dynamics in three different latitude regions. The Northern and Southern extratropical middle atmosphere will be contrasted in its seasonal behavior, highlighting similarities and differences. The third region covered is the tropical middle atmosphere and the intraseasonal and interannual variability determining its structure.

Vertical Structure

The general vertical structure of the Earth’s atmosphere can be described using a mean temperature profile. Layers and significant levels can be identified by analyzing the height dependence of such a temperature profile (Figure 1). The lowest layer of the atmosphere is the troposphere (in Greek ‘tropos’ meaning turning) extending from the surface up to 8–17 km. Temperatures are decreasing with height and the point where the vertical gradient falls above a threshold of -2 K km^{-1} for at least 2 km is defined as the tropopause (this is the classic ‘World Meteorological Organization’ definition; other definitions also exist). The height of the tropopause varies with latitude and is lowest at the poles and highest in tropical latitudes. Above the

Figure 1 Mean temperature profile as a function of pressure/altitude. Data from Fleming et al., 1988.

tropopause temperatures are increasing with height forming the stratosphere (stratum: blanket). The stratosphere is the lower part of the middle atmosphere and extends to around 50 km. Its thermal structure is largely determined by the presence of ozone absorbing solar ultraviolet radiation. The temperature maximum in 50 km is called the stratopause. Above the stratopause temperatures are decreasing with height forming the mesosphere (in Greek 'mesos' meaning middle), the upper part of the middle atmosphere. The temperature minimum around 85 km is called the mesopause. Some 5–10 km above the mesopause temperatures start to increase rapidly. Here, in the thermosphere (in Greek 'thermos' meaning warm) region the governing physical processes change. Molecular diffusion, ionization, and ion drag become important players in determining the behavior of the layer.

In atmospheric science, height scales are often described using pressure. Geometric altitude (as used above) and pressure are related on a large scale by the hydrostatic approximation that states that the change of pressure with altitude is equal to the negative of density multiplied by the Earth's gravitational acceleration ($g = 9.81 \text{ m s}^{-2}$). Further assuming that air is an ideal gas, and using the ideal gas law together with the hydrostatic approximation, an exponential decay of pressure with height can be described. The pressure p at any given height z can be estimated by assuming a reference pressure p_0 and a constant scale height H : $p = p_0 e^{-z/H}$. The scale height H is defined as the specific gas constant for dry air ($R = 287 \text{ J kg}^{-1} \text{ K}^{-1}$) multiplied by temperature T and divided by g . Certainly, assuming a representative mean layer temperature for the middle atmosphere is a significant approximation, but works well for a general conversion between height and pressure. The value of H is usually assumed to be around 7000 m. Due to the exponential decrease of pressure (or density respectively) only $\sim 10\%$ of atmospheric mass are in the middle atmosphere.

Observations and Models

Most observations of the middle atmosphere are fairly recent. Today, measurements are obtained by balloon and rocket sondes, ground-based remote sensing (lidar or radar techniques), and satellite remote sensing. Routine balloon observations reaching the lower (stratospheric) parts of the middle atmosphere have been performed since the 1950s, mostly in the Northern Hemisphere and over land. Global temperature measurements from operational satellite instruments started around 1979 and have been complemented in recent decades by research satellite measurements. NASA's Upper Atmospheric Research Satellite contributed profoundly to our improved understanding of the middle atmosphere, measuring many quantities (including trace gases like ozone) from 1991 to 2002, as has European Space Agency's Envisat Mission from 2002 to 2012 and NASA's Aura Mission since 2004. In recent years, global meteorological analysis products have started to cover the lower part of the middle atmosphere, combining observational data and model forecasts in an optimal way to provide a best estimate of the state of the atmosphere. This is an ongoing development and expectations are that models will improve the coverage of the middle atmosphere in the future.

Zonally Averaged Meteorology

Starting from theoretical concepts the seasonal variation in the latitude–height structure of temperatures and zonal-mean zonal winds will be described. Derived quantities and their relation to the general circulation will be discussed, with a link to the full three-dimensional spatial structure of the atmosphere.

Theoretical Concepts

The vertical structure section introduced pressure as a vertical coordinate and explained the conversion between pressure and altitude using a constant scale height. Based on this approximation and the assumption that the horizontal motion in the middle atmosphere is quasi-geostrophic (large-scale horizontal winds result from a balance between pressure gradient and Coriolis force, and small deviations from this balance are considered), a set of two equations can be defined describing the averaged momentum and thermodynamic budget.

$$\frac{\partial \bar{u}}{\partial t} - f \bar{v}^* = \frac{e^{z/H}}{a \cos \phi} \nabla \cdot \mathbf{F}$$

$$\frac{\partial \bar{\Theta}}{\partial t} + \bar{\Theta}_z \bar{w}^* = Q$$

In this set of equations, $\bar{u}$ is the zonal-mean zonal velocity (west–east component of the three-dimensional velocity vector; positive for westerly (eastward) winds), f is the Coriolis parameter ($f = 2\Omega \sin \phi$; $\Omega = 2\pi/T$; $T = 86400 \text{ s}$), $a = 6.37 \cdot 10^6$ is the radius of Earth, t represents time, an overbar indicates a zonal mean, and the index z denotes a vertical derivative with respect to height. θ is the potential temperature of an air parcel. Assuming an adiabatic process, an air parcel that is moved from high altitudes to sea level would increase its temperature following the relationship

$$\Theta = T \left(\frac{p_0}{p} \right)^{R/c_p}$$

with p_0 being the pressure at sea level and the specific heat capacity at constant pressure for air $c_p = 1012 \text{ J kg}^{-1} \text{ K}^{-1}$.

The averaged momentum and thermodynamic budget equations (above) have two driving terms. The local tendency of the zonal wind (partial time derivative) is proportional to the divergence of a vector field $\mathbf{F}$ and the local (potential) temperature tendency is driven by a diabatic warming Q . Both equations have an advection term to balance the budget, with a meridional advection term for the wind and vertical advection term for the (potential) temperature tendency equation, where the (effective) meridional and vertical velocities are given by $\bar{v}^*$ and $\bar{w}^*$, respectively. This so-called residual mean circulation (or 'transformed Eulerian mean circulation' (TEM circulation)) is defined by

$$\bar{v}^* = \bar{v} - e^{z/H} \frac{\partial}{\partial z} \left(e^{-z/H} \frac{\bar{v}' \Theta'}{\bar{\Theta}_z} \right)$$

$$\bar{w}^* = \bar{w} + \frac{1}{a \cos \phi} \frac{\partial}{\partial \phi} \left(\frac{\bar{v}' \Theta'}{\bar{\Theta}_z} \cos \phi \right)$$

It is important to note that both residual velocity components, the meridional and the vertical, are linked through a continuity equation, even though this does not imply mass continuity in the system, and streamlines of the residual mean meridional circulation may in some places intersect the Earth's surface. For considerations regarding middle atmosphere dynamics this caveat is not of importance. The vector $\mathbf{F}$ is the so-called Eliassen–Palm (EP) flux and has two components

$$\mathbf{F} = \begin{pmatrix} F_{(\phi)} \\ F_{(z)} \end{pmatrix}$$

given by

$$F_{(\phi)} = -e^{-z/H} a \cos \phi \overline{u'v'}$$

$$F_{(z)} = e^{-z/H} a \cos \phi f \frac{\overline{v'\Theta'}}{\overline{\Theta}_z}$$

The meridional component ($F_{(\phi)}$) is proportional to a meridional momentum flux and the vertical component ($F_{(z)}$) is proportional to a meridional temperature flux. The divergence of this vector

$$\nabla \cdot \mathbf{F} = \frac{1}{a \cos \phi} \frac{\partial}{\partial \phi} (F_{(\phi)} \cos \phi) + \frac{\partial}{\partial z} (F_{(z)})$$

is the wave driving of the mean flow. Note that the horizontal wind and the temperature structure are linked and that this link can be expressed by a thermal wind relationship that relates vertical wind shear to the meridional temperature gradient. Therefore, the first-order driver for the overall circulation and its seasonal variation in the middle atmosphere is the radiative heating and cooling that is represented within Q . Ozone absorption of solar ultraviolet radiation is the major contributor to heating, while infrared emissions by carbon dioxide, ozone, and water vapor are cooling. The maximum heating is found in the summer hemisphere. The infrared cooling is mostly dependent on temperature and shows less latitudinal structure. The net radiative temperature change (cooling plus heating) has therefore a strong latitudinal structure, with net heating in the summer and net cooling in the winter hemisphere. This hemispheric asymmetry is the driver of the global circulation in the middle atmosphere.

Structures in Temperatures and Winds

The focus will be on the Northern and Southern Hemisphere winter seasons, and their similarities and differences in zonal-mean temperatures and zonal winds. This comparison works well in all regions of the middle atmosphere where the annual cycle is the dominant source of variability (extratropics), but does not help to elucidate tropical variability, discussed in the following subsection.

Figure 2 shows zonal mean temperatures for northern (left) and southern (right) hemisphere winter as a function of latitude and height (pressure). The tropopause, stratopause, and mesopause (from bottom to top) are indicated with small crosses. Areas of low temperatures (below 220 K) are shaded. In both seasons, the tropopause is highest at the equator and lowest at the poles, with a distinct temperature minimum around the tropical tropopause. Stratospheric polar temperatures are lower in southern winter compared to northern winter. The stratopause is highest in polar regions during winter. The lowest temperatures can be found around the summer mesopause in polar regions.

Figure 3 shows zonal-mean zonal winds for northern (left) and southern (right) hemisphere winter as a function of latitude and height (pressure). Distinct jet systems are visible in both hemispheres. Here, a jet is defined as a coherent structure with closed isolines for an absolute wind speed exceeding 20 m s^{-1} . The tropopause, stratopause, and mesopause are indicated by crosses as in **Figure 2**. Winds in the winter hemisphere are largely westerly (eastward) in the stratosphere and mesosphere. During summertime winds are easterly (westward) in this height regime. The tropopause intersects the tropospheric jets (westerly all year round). The wintertime (westerly) jets in the middle atmosphere tilt equatorward and are often referred to as Polar Night Jets (PNJs). Seasonal means cannot reproduce the wind structures in the tropical middle atmosphere well, because the wind variability is not dominated by an annual cycle. Instead variability is largest on a quasi-biennial or semiannual timescales (depending on height).

Note that even though the average flow in the middle atmosphere is westerly during wintertime, rapid deviations from the mean can occur and strong interannual variability of the PNJ on the Northern Hemisphere is well known. So-called

Figure 2 Zonal mean temperature as a function of latitude and pressure for December–January–February (DJF; left) and June–July–August (JJA; right). Crosses indicate the thermal tropopause, stratopause, and mesopause (from bottom to top). Data from Fleming et al., 1988.

Figure 3 Zonal-mean zonal wind as a function of latitude and pressure for December–January–February (DJF; left) and June–July–August (JJA; right). Crosses indicate the thermal tropopause, stratopause, and mesopause (from bottom to top). Data from Fleming et al., 1988.

major stratospheric sudden warmings (SSWs) are linked to a reversal of the meridional temperature gradient, with stratospheric temperatures over the poles strongly increasing, and a wind reversal to easterlies in middle latitudes. The SSWs develop rapidly over a couple of days and recover over a time-scale of weeks and occur occasionally during Northern Hemisphere winter. Only one major SSW has so far been observed on the Southern Hemisphere during 2002.

Tropical Circulation (Quasi-Biennial Oscillation and Semiannual Oscillation)

In contrast to the extratropical middle atmosphere, the annual cycle is not a very dominant mode of variability in tropical latitudes. Intraseasonal and interseasonal variations are the more dominant modes of variability there. By looking at seasonal averages so far, most of the variability dominating the middle atmosphere in the tropics has been averaged out.

Figure 4 shows the zonal-mean zonal wind averaged over tropical latitudes as a function of time and height (pressure). Between 3 and 100 hPa, a quasi-periodic change of westerly and easterly (gray shaded) winds is apparent. This quasi-biennial oscillation (QBO) is largely driven by tropical waves and has an approximate periodicity of 26–28 months. The

easterly wind extremum (approximately -30 m s^{-1}) is usually stronger in magnitude than the westerly wind maximum ($\sim 15 \text{ m s}^{-1}$) and the successive phases of the QBO descend slowly ($\sim 1 \text{ km}$ per month) from the upper to the lower stratosphere. Generally, westerly winds descend more regularly and quicker than easterly winds that occasionally stop descending for a few weeks before continuing to propagate further down. Note that the westerly winds at the equator have greater angular momentum than the rotating Earth; this is an additional evidence for tropical wave forcing causing the QBO. There is a weak link to the seasonal cycle, with the onset of westerly winds in the upper stratosphere being somewhat linked to the descending westerly phase of the semiannual oscillation (SAO). The SAO near the stratopause manifest itself in a twice-yearly wind reversal (there is a mesopause SAO as well that is out of phase with the stratopause SAO) and is the dominant mode of variability in the middle atmosphere above 3 hPa for latitudes from 30° S to 30° N . It is forced by waves and momentum advection. The amplitude during the first half of the calendar year usually exceeds the amplitude in the second half. This is linked to the stronger extratropical wave forcing during the Northern Hemisphere winter, discussed below. The descending shear zones (westerly over easterly winds or vice versa) of the QBO modulate the thermal structure

Figure 4 Equatorial zonal-mean zonal wind as a function of time and pressure. Data shown is monthly; year labels indicate beginning of the year; data from ERA-Interim. Data from Fleming et al., 1988.

of the tropical stratosphere and the ascending branch of the Brewer–Dobson circulation (BDC, discussed below). Even though the QBO itself is narrow in latitudinal extent (15°S – 15°N) it affects the middle atmosphere circulation on a hemispheric to global scale by, for example, influencing the propagation of planetary waves. Links between planetary waves and the hemispheric circulation patterns are discussed in the next section.

Large-Scale Waves and Forcing

Wave forcing and its impact on the mean circulation have already been mentioned in the theoretical section. This section will illustrate features of extratropical planetary waves in the lower middle atmosphere, highlighting important hemispheric asymmetries.

Figure 5 shows the zonal-mean zonal wind as a function of latitude and height (pressure) for both winter seasons (left) and the amplitude of planetary wave 1 (PW1; right) correspondingly. The wave amplitudes shown are the results of a Fourier decomposition of geopotential height (the height at which a certain pressure occurs). The gradient of the geopotential height determines the horizontal wind on a constant pressure surface (geostrophic approximation, see above). The data used to compile this figure is the ERA-Interim reanalysis data set. The data are produced by a state-of-the-art meteorological model, which is constrained using observational data to produce a best-guess of the state of the atmosphere at any given time. The current data set covers the period 1979 to present. So far, only the lower part of the middle atmosphere (stratosphere) is covered. As in Figure 3 the tropospheric and stratospheric jets are well captured. The hemispheric asymmetry in stratospheric jet strength is obvious, with winds exceeding 80 m s^{-1} on the Southern Hemisphere and only just reaching 60 m s^{-1} in the upper part of the stratosphere on the Northern Hemisphere. Planetary wave amplitudes are very different. The wave amplitude for a planetary wave of wave number 1 (PW1; one trough and one ridge along a longitude circle) is lower on the Southern Hemisphere ($\sim 400\text{ m}$) compared to the Northern Hemisphere. The vertical propagation of planetary waves from the upper troposphere to the stratosphere requires winds to be

westerly and not too strong (Charney–Drazin criterion). So the lower amplitude on the Southern Hemisphere is consistent with less excitation (the flow is more zonal, because of fewer orographic features in the Southern Hemisphere), and the stronger jet (the conditions for propagation are less favorable in the stratosphere). Certainly one leads to the other and larger wave amplitudes would cause a more disturbed and therefore a weaker averaged jet.

Even though a model can never fully capture reality, model output of a chemistry–climate model has been used to generate Figures 6 and 7. The model captures the principal climatological features well and provides a self-consistent description of the atmospheric flow. Here, the emphasis is on the linkages between different elements of the circulation and transport as described in the theory section.

Figure 6 shows the EP flux (see above for definition, scaled arrows) and the deceleration of the mean flow (isolines) due to resolved planetary waves as a function of latitude and height (pressure) for Northern Hemisphere winter (left) and Southern Hemisphere winter (right). The fluxes are generally upward and equatorward (where sizable with respect to the decreasing density), in line with the propagation properties of planetary waves. The deceleration is most prominent during Northern Hemisphere winter in the upper stratosphere and lower mesosphere, with much smaller values on the Southern Hemisphere during winter. This is consistent with the jet asymmetry discussed above; where deceleration is larger and the jet is weaker.

Structures in Meridional Circulation and Tracers

The residual circulation of the middle atmosphere cannot be measured directly. It can be inferred from observations with the help of models (e.g., using a data assimilation system), or it can be assessed analyzing the concentration of long-lived trace gases.

In the previous section, we focused largely on zonal-mean zonal winds and the related temperature structures. As discussed in the theory section, the slower effective vertical and meridional motion (south–north) is important as well and determines the distribution of long-lived trace gases like

Figure 5 Zonal-mean zonal wind for the winter season as a function of latitude and pressure (left). Figure 7 Residual circulation velocity vectors (scaled arrows) and isopleths of a long-lived tracer (isolines) as a function of latitude and pressure for December–January–February (DJF; left) and June–July–August (JJA; right). Data from a chemistry–climate model for internal consistency. Data from Fleming et al., 1988.

nitrous oxide (N_2O ; lifetime ~ 120 years) and methane (CH_4 ; lifetime ~ 10 years).

Figure 7 shows the TEM circulation (for definition see theory section above) with scaled arrows as a function of latitude and height (pressure) for the Northern (left) and Southern (right) Hemisphere winter. Overlaid are selected isolines of a long-lived tracer (N_2O). The above troposphere part of the TEM circulation is referred to as the BDC. It is shaping the tracer distribution of long-lived tracers in the stratosphere and mesosphere.

As can be seen from Figure 7, the ascending branch of the BDC is on the summer hemisphere, with a maximum in the subtropical middle atmosphere. Ascend is slow above the tropopause and accelerates toward the upper part of the stratosphere. While ascending, air flows predominantly to the winter pole where it descends. This overturning motion determines the meridional gradients of long-lived tracers in the winter hemisphere. Tracers with high tropospheric values (e.g., N_2O) indicate the ascending branch of the BDC by a relative concentration maximum at a given height. Isolines of tracer concentrations slope down poleward and their vertical gradient increases (Figure 7). The slope is not uniform and often shows a stepwise behavior in the subtropics and toward higher latitudes. This flattening of the slope is caused by quasi-horizontal

mixing. Even though we cannot measure the BDC directly as a velocity field, we can infer its behavior from trace gas observations. Probability density functions, as a function of potential temperature, can help to visualize different flow regimes, and trends of very inert tracers with clearly identified tropospheric sources (e.g., SF_6) can help to assess possible trends in the BDC. This is usually done by deriving a so-called age-of-air, a measure for the time an air parcel has spend in the stratosphere since entering through the tropical tropopause. Current models indicate that the BDC will strengthen under climate change (decreasing age-of-air), but strong observational evidence for this model result is still missing.

Concluding Remarks

This article summarizes the theoretical basis, observational evidence (including reanalysis data), and some model applications for characterizing and explaining the zonal mean structure and circulation of the middle atmosphere. The basic understanding of the middle atmosphere circulation is good, but some open questions remain, in particular regarding trends in the BDC. Satellite observations and advances in modeling (including data assimilation) will help to grow our

understanding further. Even though the zonal mean approach for describing atmospheric circulation is extremely useful, it is important to keep the full spatial complexity in mind when discussing rapidly changing flow regimes, for example (major) sudden stratospheric warmings.

Introduction

Mountain meteorology is the study of how mountains modify weather and climate. The subject is as old as meteorology itself. Aristotle's *Meteorologica* (c. 340 BC) included the (incorrect) speculation that mountains control the altitude range in which clouds form. Pascal's 1648 measurement of how the air pressure decreases with altitude on Puy de Dome in southern France addressed some of the most profound issues in meteorology: the weight and compressibility of air. Throughout the age of exploration, travelers and geographers described and tried to understand the various influences of mountains on climate: the temperature lapse rate (i.e., tree line, snow line, and high-altitude tundra and glaciers), reversed winds on hilltops, mountaintop clouds, wet–dry contrast across mountain ranges, the triggering of convection by hills, sheltering from winds on steep lee slopes, and gap winds. Some scholars would argue that the scientific study of mountain meteorology began with the extensive measurements of the physical conditions around Mt Blanc in the Alps by HB Saussure (1740–99) or with the reports on mountains and climate in South America and Asia by A von Humboldt (1769–1859). In the nineteenth century, most meteorology texts by authors in Europe and America contained sections on mountain climate, including those by Kaemtz from Halle (1844), Maury from Washington, DC (1855), Loomis from New Haven (1868), Tyndall from London (1872), Flammarion from Paris (1874),

and Ferrel from Kansas City (1889). In the twentieth century, as mathematical models of the atmosphere advanced, and our ability to observe the atmosphere quantitatively has improved, our understanding of the influence of mountains on the atmosphere has grown exponentially.

The subject of mountain meteorology is connected with the broader fields of ecology and geology in several ways. Many of the Earth's deserts are caused by the barrier effects of mountain ranges. Rain forests often occur on windward mountain slopes. Local ocean circulations are influenced by the cold air reaching the sea through mountain passes, and by the freshwater input to the oceans, channeled by the terrain. Major continental ice sheets have grown from small mountain glaciers. The shape and height of the mountains themselves are controlled by the intensity of orographic rain and snow, and the subsequent eroding action of stream flow and glacial scraping. Mountain meteorology is also important in human affairs, and thus there is continuing research to improve the forecasting of hazardous effects of mountains: severe winds, floods, avalanches, and air pollution.

The most obvious influence of mountains on climate and vegetation is the decrease of temperature with altitude along mountain slopes. The lapse rate along mountain slopes varies somewhat with latitude, season, and aspect, but typically takes a value of $-5\text{ }^{\circ}\text{C km}^{-1}$. Thus, a 4 km high mountain would be $20\text{ }^{\circ}\text{C}$ colder than the surrounding valleys and plains. In the midlatitude temperate zone, this difference gives the

mountaintop a polar climate, with tundra, stunted vegetation, and permanent snowfields. In the tropics, however, highland climates can be quite comfortable. In low-latitude Peru, for instance, highlands in the Andes are productively farmed for barley, corn, potatoes, and fava beans. In contrast, the eastern Peruvian lowlands have excessive temperature and rains, preventing proper soil development. The western Peruvian lowlands are an unproductive coastal desert.

The challenge and richness of the field of mountain meteorology are due in part to the fractal nature of the Earth's terrain. Major mountain ranges such as the Rockies, Andes, Himalayas, and Alps have horizontal dimensions of 1000 km, yet they contain within themselves a hierarchy of smaller scales down to at least 100 m: a factor of 10 000 in physical size. The heights of mountains vary from an arbitrary minimum of 100 m to nearly 10 km: a factor of 100. The orientations of mountain ranges also vary with respect to both the direction of the prevailing winds and the Sun's rays. The geographical position of each mountain range is highly significant, as the physical characteristics of the environment influence the way mountains modify the climate. For example, mountains in the tropics may trigger convection and thunderstorms owing to the unstable nature of a warm, moist air column, while high-latitude mountains will force smooth uplift with enhanced stratus rain and snow.

It is interesting to note that the height of the Earth's highest mountain (8.8 km) is only about one-tenth of one percent of the Earth's radius (6280 km). Thus, the Earth is nearly as smooth as the proverbial billiard ball. Given this fact, the importance of mountains on weather and climate is somewhat surprising. A partial answer to this paradox is that the Earth's atmosphere is also rather shallow with a density scale height of 8.5 km. Thus, the largest mountains reach to altitudes above most of the atmospheric mass. A more careful physical analysis allows us to identify four specific reasons for the importance of mountains in the atmosphere. These are discussed below.

Stable Stratification and Buoyancy Forces

A remarkable property of the atmosphere is its static stability, that is, an inherent resistance to vertical air motion. This stability arises from its typical temperature lapse rate ($\gamma = -6.5^\circ\text{C km}^{-1}$), which is greater than the adiabatic lapse rate ($\Gamma = -9.8^\circ\text{C km}^{-1}$). The magnitude of the static stability is characterized by the buoyancy frequency $N = [g(\gamma - \Gamma)/T]^{1/2} = 0.01\text{ s}^{-1}$, where g is the acceleration of gravity and T is the air temperature. A parcel of air displaced upward will return to its original level owing to buoyancy forces in a time $t = N^{-1}$: about 600 s or 10 min. The influence of this stability on airflow over mountains is an essential aspect of mountain meteorology.

The static stability of the atmosphere resists vertical motion, while mountain slopes try to generate vertical motion. If the mountain height is modest and the wind is strong, air will be able to climb the windward slope and reach the hilltop. In its effort to restore the air parcels to their original altitude, the buoyancy force causes the air to overshoot its equilibrium position, bringing the air rapidly down the lee slope and generating mountain waves. Through the action of mountain waves, the influence of the terrain may be felt at great vertical

and horizontal distances from the generating terrain. Mountain waves have been the subject of intensive study since the 1930s. They are of two types: vertically propagating and trapped waves. Vertically propagating mountain waves can be found at great altitudes above the mountain, even in the stratosphere (Figures 1 and 2). They usually have an irregular pattern, with a poorly defined wavelength longer than 15 km. Trapped mountain waves can occur under conditions when the Scorer parameter (the ratio of the buoyancy frequency to the wind speed) decreases with altitude, as is the case with a strong jet stream and reduced static stability in the upper troposphere. Trapped waves occur in the form of beautifully periodic waves, with wavelength from 8 to 25 km, extending 100 km or more downstream of a mountain ridge. Mathematically, trapped lee waves arise from a resonance in which internal gravity waves reflected downward by the jet stream are reflected upward again by the Earth's surface.

For higher hills or slower winds, the air may be unable to rise over the terrain or, if it does so, may generate nonlinear breaking mountain waves and turbulence. Over a long ridge, mountain wave breaking causes a transition from weak mountain waves to a strong downslope flow situation. Good examples are the Foehn in the Alps, the westerly Chinook windstorm in Colorado, and the northeasterly Bora over the Adriatic Sea. A long ridge may also create a barrier jet, an air current along the windward slope, to the left or right of the incident airstream, depending on whether the mountain lies in the Northern or Southern Hemisphere. Near isolated peaks or ridges with gaps, the airflow is forced to split and divert around the mountain causing corner or gap winds. The most famous flow splitting/gap flow phenomenon is the Mistral, a northerly wind reaching the Gulf of Lyon between the Pyrenees and the Alps. Severe downslope and gap winds can cause damage to crops and structures. Isolated high hills may generate vorticity by the action of breaking gravity waves or by sloping boundary layers. This vorticity sheds downstream to create steady or oscillating vortex wakes. The big island of Hawaii, during the steady summer Trade Winds, produces two large counter-rotating eddies in its lee (Figure 3). The small Caribbean island of St Vincent generates a long, straight wake extending for 400 km toward the coast of Central America.

Under the simplest of situations, a single parameter, the nondimensional mountain height ($H = hN/U$), is a controlling quantity in mountain airflow dynamics. In the definition of H , h is the mountain height, N is the buoyancy frequency, and U is the ambient wind speed. If $H < 1$, laminar mountain waves will exist. If $H > 1$, wave breaking or flow splitting will occur. As an example, if $N = 0.01\text{ s}^{-1}$ and $U = 10\text{ m s}^{-1}$ a mountain height of 500 m (i.e., $H = 0.5$) would generate weak mountain waves, while a mountain height of 2000 m (i.e., $H = 2$) would generate severe downslope winds or barrier jets and gap winds.

Condensation of Water Vapor

Another property of the atmosphere that sensitizes it to mountain effects is its high water vapor content. A typical relative humidity in the Earth's lower atmosphere is 70–80%. This level of humidity is maintained by a global balance between evaporation from the oceans and land, and

Figure 1 Mountain waves over Mt Blanc in the Alps. This diagram shows a vertical cross section of the troposphere aligned southwest to northeast over the peak of Mt Blanc. The ambient wind is from left to right in the diagram. Vertically propagating waves are seen from the disturbed patterns of clouds and from the vertical air motion sensed by a research aircraft. precipitation from clouds. With such humid air, only a few hundred meters of uplift and adiabatic cooling are needed to bring the air to saturation. Thus, airflow over mountains is often associated with fog, clouds, and precipitation.

While the basic thermodynamics of the ascent of a moist parcel has been known for more than a century, the physics of orographic precipitation is poorly understood and probably varies considerably with physical scale and climatic setting. One key issue is whether clouds generated by mountain uplift can precipitate. In the 1950s, T Bergeron, a Swedish cloud physicist, pointed out that, for narrow hills and moderate wind speeds, air parcels spend so little time over the hill that there is insufficient time to convert the cloud droplets to larger precipitation-sized particles. Under this condition, orographic clouds cannot produce precipitation themselves but can only amplify existing broad-scale precipitation by a droplet scavenging process.

For midlatitude mountain ranges with widths exceeding 50 km (e.g., the Sierras, the Alps, the Southern Alps, and the Andes), the transit time across the range is sufficient for hydrometeors to form. During episodes of strong moist airflow against the range, the upslope regions experience heavy rain and/or snow. The leeward slopes in contrast experience dry, clear, descending flow – the rain shadow. In the northern midlatitude belt of westerlies, the Rocky Mountains lie across the prevailing airstream. Large annual precipitation is found on the western side (i.e., Oregon and Washington states), while

a drier climate is found in the High Plains of Wyoming and Colorado. In Europe, the mountains of Scandinavia produce a wet climate in Bergen, Norway, and drier climates downstream in Oslo and Stockholm. The Alps, oriented in an east-west direction, experience wet-dry contrast during short periods of southerly or northerly flow, but no systematic climate contrast. No better example of this phenomenon exists than in the southern Andes, between latitudes 30° S and 50° S. Exposed to the prevailing westerlies in the Southern Hemisphere, the western side of the Andes receives several meters of annual rainfall, while the eastern side is dry. The south island of New Zealand provides another clear example of a wet-dry contrast. The quantitative estimation of how much water can cross over a high mountain range is still a topic of research. Spillover or drift of hydrometeors is one way in which water can bypass the effective 'cold-trap' presented by a high mountain. Another bypass mechanism is airflow through gaps. Air that finds a route through a gap is neither lifted as high nor chilled as much as air that rises over the highest peaks.

In lower latitudes, or in summer, the air column tends to be less stable to moist ascent, and the perturbing influence of mountains triggers convection. Examples of orographic triggering have been studied in Hawaii, Taiwan, and on the south side of the Alps in Italy. Convective showers over steep terrain are dangerous as the heavy rainfall can be channeled quickly into flash floods.

Solar Radiation

Another atmospheric response to mountains is caused by an uneven warming by solar radiation. An isolated mountaintop, for example, subjected to the Sun's rays, will normally develop a surface temperature that is warmer than the free atmosphere at the same elevation. The resulting horizontal temperature

gradient will generate a circulation between the hilltop and surrounding area. A good example of this thermal circulation is the daily buildup of convective clouds over the peaks in the Rocky Mountains in summer. Hikers are advised to reach the peaks by noon and start down, thus avoiding the electrical discharges from afternoon convective clouds. An opposite circulation might occur if the hilltop is snow-covered, so that it reflects most of the Sun's radiation.

Another terrain geometry of interest is the deep valley. Because of the volume displaced by the valley walls, the sunlight absorbed per unit horizontal area is used to warm a smaller volume of air than would be the case in flat terrain, thus raising the temperature more. This effect can generate a differential warming between the valley and adjacent plain, or between sections of the valley with different widths or wall steepnesses. The resulting temperature difference can generate an up-axis 'valley wind'. At night, the process is reversed and a down-axis 'mountain wind' can occur. These mountain-valley circulations are predictable and reliable, modulated mostly by the cloud cover shielding the Sun and by the seasons, varying the Sun angle.

Interesting enhancements and asymmetries in thermally driven mountain flows can occur if the Sun angle is low. Consider for example, an east-west ridge with north- and south-facing slopes, tilted at 22° from the horizontal. At a latitude of 45° north in the winter, the Sun lies about 68° south of the zenith point at local noon. Rays from the Sun would strike the south face of the ridge at 46° from normal incidence. The irradiance falling on the hillslope is given by the product of the solar constant (S) and the cosine of the angle between the Sun's rays and the direction perpendicular to the surface. For the example at hand, the irradiance on the sunlit slope is $S \cos(46^\circ) = (1380) (0.69) = 958 \text{ W m}^{-2}$. In contrast, the north-facing slope would experience tangential rays and thus collect zero irradiance. This differential heating between north- and south-facing slopes will generate its own thermal

Figure 4 The stationary pattern of planetary waves induced by the surface irregularities of the Earth – oceans, continents, and mountains. These meandering bends in the jet stream and polar front control midlatitude weather. This diagram shows the southerly component of the wind vector, as a function of longitude and height. The contours are labeled with wind speed in meters per second. Reproduced from Manabe, S., Terpstra, T.B. circulation, rising air on the heated slope and descending air along the slope in shadow. The heated air may rise above the hilltop to generate cumulus clouds.

Coriolis Force and Large-Scale Planetary Waves

One of the most interesting, but least understood, mountain effects on climate is the influence of major mountain ranges on the midlatitude planetary waves. The term ‘planetary wave’ here refers to the north–south meandering of the westerly jet stream and polar front around the globe (Figure 4). The wavelength of these waves ranges from 5000 to 20 000 km. The week-by-week location of the crests and troughs of the planetary waves modulates the temperatures and storminess of sites around the world.

It was suggested by J Charney and A Eliassen in the 1960s that the Rocky Mountains and the Tibetan Plateau could, through a Coriolis force mechanism, generate standing planetary waves in the Northern Hemisphere that would have their own influence on global climate and would interact with drifting planetary waves generated by other processes. This suggestion has received considerable attention from researchers using general circulation models (GCMs), including a clever mountain (M)/no-mountain (NM) comparison technique. The basis of this method is a supercomputer-based GCM that has been tested for its ability to predict, from first principles, the statistics of the planetary wave structure in the Earth’s atmosphere. With such a numerical model, it is a relatively simple matter to remove the Earth’s mountains from the lower boundary conditions of the model. Comparing the M and the NM runs allows one to determine the role of the mountains in the distribution of climate. The results indicate that, indeed, the amplitude and phase of planetary waves are significantly influenced by the major mountain ranges.

This result is of more than theoretical interest. Over the 4.6 billion year history of the Earth, mountain belts have been created and destroyed by repeated cycles of crustal plate collision and erosion. Thus, in addition to other climate influences such as the variations in solar intensity, orbital parameters, and atmospheric composition, the changing distribution of mountains could have modified the Earth’s climate. On the shorter timescale of a hundred thousand years, large continental glaciers

have cyclically grown and decayed. A good example is the Laurentide ice sheet in eastern Canada. These massive ice sheets behave much like mountain ranges, altering both local and global climates. The Greenland ice cap, with its peak altitude near 2800 m, plays a significant role today in modifying weather patterns and trapping water vapor in the North Atlantic region.

In the future, mountain meteorology will continue to challenge scientists with the chaotic nature of its fluid dynamics and the sensitivity of orographic effects to the precise details of the ambient flow and solar radiation fields. Powerful new observational tools such as remote sensing radar and lidar will allow three-dimensional airflow and cloud fields to be mapped. Numerical models with ever-increasing spatial resolution, run on supercomputers, will stimulate research on nonlinearity and the complex interactions between fluid dynamics, cloud physics, and radiation. If successful, these investigations will lead to improved weather prediction and increased understanding of ancient and modern climates.

Cold Air Damming

BA Colle, Stony Brook University – SUNY, Stony Brook, NY, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Cold air damming (CAD) occurs when cold, stable air becomes topographically blocked by relatively long, continuous mountain ranges. The cold air becomes rotationally trapped against the mountain to form a pressure wedge and low-level jet parallel to the barrier. The cold dome can be further modified by diabatic processes within the planetary boundary layer. This article summarizes the structure and evolution of CAD. The large-scale flow patterns that favor CAD are highlighted, with particular emphasis on the Appalachian Mountains and Rocky Mountains. Finally, some of the societal impacts and forecast challenges are discussed.

Introduction

Cold air damming (CAD) is the process whereby cold, stable air becomes topographically blocked and channeled adjacent to a mountain range. This results in a cold dome along the barrier, which can often be identified by a pronounced U-shaped 'wedge' in the sea-level pressure pattern (Figure 1(a)), and an enhancement in the terrain-parallel flow adjacent to the mountain slope (Figure 1(b)), commonly referred to as a barrier jet. The temperatures within the damming region are often 5–10 °C cooler than surrounding areas of equal elevation (Figure 1(a)). Damming events typically occur during the cold season when an along-barrier pressure gradient is created by a cold anticyclone passing to the north (south) of the barrier slope in the Northern (Southern) Hemisphere. When the favorable synoptic conditions persist, the cold air mass is often observed to remain in a quasi-steady state.

Long, continuous mountain ranges obstruct the low-level flow of cold air and can result in CAD. The structure and evolution of CADs are determined by the ambient flow speed and direction approaching the barrier, terrain height, low-level density stratification, diabatic effects, and latitude. The terrain-normal wind speeds, stratification, and terrain height determine whether the low-level flow is blocked by the barrier. Since CAD events typically last more than several hours, planetary rotation limits the horizontal extent of the damming and determines the evolution of the momentum balances near the terrain. Diabatic effects such as evaporative cooling and melting can also modify the CAD evolution.

CAD is common along many mountainous regions around the world such as the Appalachians and Rockies in North America. The development of the cold dome during these events results in several operational forecast challenges such as precipitation type (freezing rain, sleet, snow), precipitation enhancement along 'coastal fronts' and from ascent over the cold dome, stratus/fog, and unseasonably cold weather. Numerical models at moderate resolution (<30 km grid spacing) can resolve CAD events, but there are forecast challenges associated with the strength and dissipation of these events.

Nondimensional Flow Parameters

CAD is dependent on the amount of cold air blocked by an elongated mountain range. Flow blocking by a barrier is related to the ratio of the kinetic energy of the ambient flow to the potential energy needed to get a near surface air parcel over the mountaintop. This ratio is given by the Froude number, Fr , where

$$Fr = U/(NH). \quad [1]$$

In eqn [1], U is the speed of the average flow impinging toward the barrier below crest level, N is the Brunt–Väisälä frequency, and H is the mountain height. Fr^2 may be interpreted as the ratio of inertial forces, $U(U/H)$, to buoyancy forces, N^2H . The square of the stability, $N^2 = g/\theta_o(\Delta\theta/\Delta z)$, for these events is often given as the reduced gravity ($g' = g/\theta_o(\Delta\theta)$) divided by the depth over which $\Delta\theta$ is evaluated, since there is frequently an inversion capping the CAD. The average potential temperature beneath the inversion is given by θ_o . A large Froude number ($Fr > 1$) indicates that the flow has enough kinetic energy to surmount the barrier, while low Froude number ($Fr < 1$) favors blocked flow along the barrier. Many CAD episodes are characterized by an Fr less than 0.5, which is an indicative of significant flow blocking.

In the rotating limit (i.e., when Coriolis effects are to be considered), theoretical studies have shown that the Burger number ($B = HN/Lf$, where L is the mountain half-width and f is the Coriolis parameter) is also an important parameter to diagnose potential blocking. For situations of equal stratification and latitude, the Burger number is proportional to the steepness of the mountain slope (H/L). When $B < 1$, the flow is quasi-geostrophic/semigeostrophic and the flow can pass over the mountain; however, when $B > 1$, the barrier is considered to be 'hydrodynamically steep' and the flow is blocked by the barrier and begins to flow down the pressure gradient (Figure 2(a)).

When $Fr < 1$ or $B > 1$, blocked ageostrophic downgradient flow is forced by an along-barrier pressure gradient imposed by the synoptic-scale pressure field (Figure 2). Using scale analysis on the momentum equations, when l/L (cross-barrier length scale/along-barrier length scale) is small and the Rossby number $R_l = V/fl$ (where V is the magnitude of the along-barrier flow) is approximately equal to or greater than one, the winds

are primarily terrain-parallel within approximately a Rossby radius of deformation, $l_R = (g'H)^{1/2}/f$, of the barrier. For example, for the Appalachian Mountains of North America, l_R is typically around 150 km (where $H \sim 1000$ m, $g' \sim 0.25 \text{ m s}^{-2}$, and $f \sim 10^{-4} \text{ s}^{-1}$).

Within a Rossby radius of the terrain, an antitriptic balance typically develops in the along-barrier direction between friction and the pressure gradient (Figure 2(b)). Meanwhile, in the cross-barrier direction the mass field adjusts under the influence of rotation (e.g., geostrophic adjustment) such that the pressure gradient normal to the terrain balances the Coriolis force associated with the terrain-parallel winds. Since the Rossby radius depends on the latitude (as defined by f), CAD is

able to extend further away from the barrier closer to the equator given identical stratification and mountain height.

Structure and Evolution

Antecedent Conditions

The interaction of the synoptic-scale flow with an elongated mountain barrier acts to initiate CAD. Typically, significant damming events are associated with an upper level trough and associated cold surface anticyclone crossing immediately to the north (south) of the barrier in the Northern (Southern) Hemisphere (Figure 3(a)). (For purposes of illustration, only

Figure 2 Illustration of the development of flow blocking in which (a) an along-barrier pressure gradient develops adjacent to a mountain (Northern Hemisphere) and a parcel well upstream of the mountain is nearly geostrophic; (b) subsequently, through flow blocking and geostrophic adjustment, a mesoscale pressure ridge develops adjacent to the mountain within a Rossby radius of deformation, and the flow has an antitropic balance in the along-barrier direction and nearly geostrophic in the cross-barrier direction.

the evolution CAD in the Northern Hemisphere is shown.) For damming along the Appalachians, there is often split westerly flow aloft, with a secondary upper level trough and associated surface cyclone situated to the southwest of the barrier. For other barriers such as the Rocky Mountains and Andes, significant cross-barrier flow at crest level to the south of the anticyclone often results in downslope warming and a lee trough (Figure 3(a)). For either situation, this high–low pressure couplet enhances the along-barrier pressure gradient.

Initiation and Mature Phases

When the low-level cold air around the anticyclone becomes blocked along the slope ($Fr < 1$), the along-barrier pressure gradient results in ageostrophic nearly terrain-parallel flow adjacent to the barrier (Figure 3(a) and 3(b)), which advects cold air southward along the barrier slope. Meanwhile, above the mountain there may be neutral or even warm advection. Because of the significant cold air source to the north, cold advection is typically much larger than upslope adiabatic cooling during damming events. The rapid decrease in cold advection with height results in a shallow cold air dome capped by an isothermal or inversion layer, which increases the stability and enhances the flow blocking. Meanwhile, a Coriolis torque acting on this downgradient flow results in an upslope flow component near the barrier slope, which helps push cold

air up the mountain slope. For some cases, the synoptic-scale low-level flow will also have a geostrophic wind component directed toward the barrier.

Because of the significant low-level stability and significant mountain slope, the Froude number (Fr) is typically $\ll 1$ and Burger number (B) is $\gg 1$, which results in blocking of the cold air before it reaches the mountaintop. This blocking prevents the development of geostrophic balance in the along-barrier direction and a wedge of cold air (cold dome) develops adjacent to the mountain. This cold dome hydrostatically results in a pressure ridge along the barrier, which extends a Rossby radius (l_R) upstream of the crest (Figure 3(c)). In the along-barrier direction, the flow becomes balanced by the pressure gradient and friction processes. Because of the strong static stability and weak vertical mixing, most of the friction is the result of surface drag. In the cross-barrier direction, a geostrophic balance develops between the cross-barrier pressure gradient and the Coriolis force.

To demonstrate this adjustment process and vertical structure of the damming process, Figure 4 shows the horizontal flow and thermal evolution in a cross section taken normal to the mountain range. Prior to the CAD event, the isentropes are nearly horizontal adjacent to the mountain with fairly weak stability near crest level. For many cases, there may be a preexisting cold stable layer from a previous damming event or a depression in the isentropes from adiabatic warming associated with downslope flow (Figure 4(a)). At this initial time, there is little flow in the along-barrier direction. Once the along-barrier pressure gradient becomes more established, ageostrophic northerlies develop and the Coriolis force turns the flow in an upslope direction (Figure 4(b)). The isentropes begin to tilt in response to the cold air being advected up the barrier. The low-level cold advection and weak upslope cooling combined with neutral or warm advection above results in a stable layer intensifying near the top of the cold dome.

During the next few hours, the mass field associated with the blocked flow adjusts to planetary rotation and extends approximately a Rossby radius upstream of the barrier (Figure 4(c)). By this time, CAD and the cold dome are firmly established adjacent to the barrier. The cold dome is deepest near the bottom of the slope, which hydrostatically corresponds to the axis of the sea-level pressure ridge (Figure 3(b)). The damming regime is often characterized by neutral or conditionally unstable lapse rates in the lower layer (cold dome) and is capped by an inversion. The terrain-parallel flow within this cold dome is maximized where the greatest tilt of the isentropes and resulting cross-barrier pressure gradient exist. The core of maximum winds (labeled J in Figure 4(c)), which can frequently exceed 20 m s^{-1} , is often referred to as a ‘barrier jet.’ The development of the barrier jet feeds more cold air into the damming region, therefore helping to sustain the cold dome.

The cold dome and barrier jet associated with damming persist as long as there is a cold air source feeding the cold dome. Meanwhile, strong warm advection may occur to the east and over the cold dome (not shown), which increases the inversion at the top of the cold dome and reduces the vertical mixing between the CAD layer and the ambient flow above. There is often ascent of relatively warmer air up and over the

Figure 3 Horizontal evolution of CAD for the (a) initiation, (b) development, (c) mature, and (d) decay stages. Sea-level pressure (solid, every 4 mb), temperature (dashed, every 5 °C), and surface winds are shown. Line segment AB in (a) is the location of the cross section shown in Figure 4.

CAD cold dome, which can enhance the precipitation upstream of the mountain slope. For some events such as Appalachian damming, precipitation falling from the saturated flow over the cold dome results in evaporative cooling and further strengthening or maintenance of the cold dome.

Dissipation Phase

CAD dissipates when the cold surface anticyclone moves away from the barrier, and the cold air source is lost (Figure 3(d)). There are five processes that can contribute to CAD weakening: (1) Cold advection just above the mountain crest can reduce the strength of the inversion capping the cold dome and thus reduce the potential for flow blocking; (2) Solar heating, if there are limited clouds within the cold dome; (3) Near surface divergence, as pressure falls occur to the north of the barrier and the developing southerly flow is directed more opposite from the terrain-parallel flow to the south (in the Northern Hemisphere). This divergence can also reduce the cloud cover and increase the weakening from solar heating; (4) Shear-induced mixing of potentially warmer air from aloft can weaken the cold dome from the top down; and (5) An approaching warm or coastal front that mixes out the relatively shallow cold dome. In some locations, particularly for large mountain barriers such as the Rockies and the Himalayas, the cold dome may be eroded by significant

cross-barrier and downslope flow near crest level (e.g., ‘Chinook’ or ‘Foehn’ winds).

CAD Types

A few CAD damming evolutions have been identified for the Appalachian Mountains, which are related to the intensity of the CAD and the role of diabatic processes (Figure 5). The classification includes (1) Classical damming initiated by the interaction of synoptic-scale features with topography, but little diabatic processes; (2) Classical events that develop more *in situ* as a result of diabatic cooling processes (evaporation as precipitation falls into dry air); and (3) Hybrid events in which both (1) and (2) are prevalent.

The classical CAD has a large anticyclone located over the Northeast United States during the peak strength of CAD (Figure 5(b)). This surface high pressure is associated with an anomalous shortwave ridge at 500 hPa from southeast Canada to the southeastern US coast (Figure 5(d)), and a midlevel trough over the Central United States. The jet streak at 250 hPa extends eastward from the Northeast United States in a region of confluent flow to the east of the upper level ridge axis (Figure 5(a)). A surface high-pressure ridge extends southward to the east of the Appalachians (Figure 5(b)), with nearly terrain-parallel flow near the surface (not shown). Meanwhile,

Figure 4 Vertical evolution of CAD for the (a) initiation, (b) development, and (c) mature stages for cross section AB showing the potential temperature (solid, every 4 K) and horizontal winds in the section. The location of AB is shown in [Figure 3\(a\)](#). The letter 'J' shows the position of the terrain-parallel barrier jet.

Figure 5 The CAD spectrum defined with respect to event intensity and the relative contribution of synoptic-scale dry forcing and diabatic processes. From Figure 2(b) in Bailey, C.M., Hartfield, G., Lackmann, G.M., Keeter, K., Sharp, S., 2003. An objective climatology, classification scheme, and assessment of sensible weather impacts for Appalachian cold-air damming. *Weather Forecasting* 18, 641–661. © American Meteorological Society. Reprinted with permission.

the pressure ridge at 850 hPa is centered over the Northeast United States and to the east of the Southeast United States ([Figure 5\(c\)](#)), with southwesterly flow and warm advection over the CAD.

The large-scale pattern for the hybrid CAD events is similar to that of the dry CAD events, although there are some distinct differences that result in more diabatic effects in the hybrid events. The shortwave ridge at 500 hPa is less amplified and anomalous than the dry events ([Figure 6\(b\)](#)), and there is a coupled jet structure at 250 hPa ([Figure 6\(a\)](#)), with the east of the Appalachians located in the right jet exit region along the Gulf Coast and right jet entrance region of the jet to the east of the Northeast United States. The midlevel and 850-hPa trough approaching the Appalachians is deeper in the hybrid events ([Figure 6\(c\)](#)). Meanwhile, there is a surface cyclone located over the Southeast United States ([Figure 6\(d\)](#)), with an inverted trough extending northward to the Ohio Valley. The large-scale ascent as well as moist flow around the developing cyclone ascending over the cold dome produces precipitation within the CAD region (not shown). This precipitation can enhance the cold dome through evaporative cooling and melting if the freezing level is relatively low ([Figure 7](#)).

CAD Examples around the World

There have been many documented studies of CAD around the world. The most widely studied area has been along the eastern side of the Appalachian Mountains, where the 'wedge ridge' sea-level pressure pattern is sometimes referred to as the 'Baker' ridge. Because the Appalachians are within a few hundred kilometers of the relatively warmer Atlantic Ocean, the low-level temperature gradient near the coast can be enhanced through confluence between the nearly terrain-parallel flow associated with CAD and the warmer more geostrophic flow near the coast. This frontogenetical process helps in the development of an enhanced temperature gradient near the coast called a 'coastal front.' The low-level temperature advections associated with these shallow baroclinic zones result in mixed precipitation, which can be in the form of freezing rain (ice storms) and sleet within areas of the cold dome.

CAD has recently been documented for other large mountain barriers, such as the Rockies and the Andes. For these extremely long N-S barriers, relatively cold air can propagate into tropical latitudes (10° N/S). This channeling of cold air is often referred to as a 'cold surge,' which is a cold anticyclone moving equatorward adjacent to the mountains. The primary mechanism for driving the surge southward is the development of an along-barrier pressure gradient, cold advection, and the damming evolution described above. The very high orography associated with the Rockies, Andes, and Himalayas often results in a horizontal scale of CAD that is typically much larger (>300 km) than the Appalachians and other more narrow coastal barriers. Since the Rocky Mountains are adjacent to the sloping Great Plains, flow blocking is also favored along the slope, resulting in a cold dome that extends more than 500 km east of the Rockies. As the North American surge moves southward along the mountainous Mexican coast and the large-scale slope is lost, the scale of the damming collapses to a few hundred kilometers as determined by the Rossby radius.

Figure 6 Composite of the classical dry CAD events for the Appalachians at the time of maximum onset showing: (a) 250-mb height (solid, every 12 dam) and isotachs (dashed in m s^{-1} and shaded as in legend at lower left of panel, with intervals below 40 m s^{-1} omitted); (b) 500-mb height (solid, every 6 dam), anomaly (thin contours, dashed (negative), and solid (positive); interval, 2 dam), and statistical significance (shaded as in legend at lower left); (c) 850-mb height (solid, every 3 dam), temperature (dashed; contour interval, 4°C), and relative humidity (shaded as in legend at lower left); (d) sea-level pressure (solid; contour interval, 2 hPa) and anomaly (shaded as in legend at lower left). An objective climatology, classification scheme, and assessment of sensible weather impacts for Appalachian cold-air damming. *Weather Forecasting* 18, 641–661. © American Meteorological Society. Reprinted with permission.

CAD and associated barrier jets can occur for other mountainous coastal regions, such as along Vancouver Island British Columbia, southeast Alaskan coast, east slope of the Washington Cascades, and along the Eastern Sierras. During these cases, cold air is pooled up against the barrier from a previous excursion of cold air from the interior of the continent through gaps and channels in the terrain. The along-barrier pressure gradient is often enhanced with the approach of a surface front, resulting in an enhancement of the terrain-parallel ageostrophic flow (barrier jet).

For maritime climates, such as coastal California and Australia, damming occurs when cool marine air is rotationally blocked against the coastal terrain. Typically, these events are associated with a transition from warm dry offshore flow to terrain-blocked cool marine adjacent to the coast. These coastal marine surges often result in a narrow stratus tongue that extends approximately a Rossby radius off the coast.

For many years, CAD could not be adequately resolved by operational numerical weather models, such as National Centers for Environmental Prediction's (NCEP) Nested Gridded Model and the Medium Range Forecast (MRF) Model, since

horizontal grid spacings of these models were around 30–80 km. More recent higher resolution operational or research mesoscale models (i.e., NCEP's North American Mesoscale model at 12 km resolution) are able to more realistically forecast different damming events. However, there are predictability issues regarding the strength and duration of the damming event related to difficulties in simulating the diabatic effects (radiation, evaporative cooling, and melting). In particular, numerical models often scour out the cold air too quickly and thus underestimate the duration of these CAD events.

CAD Impacts

CAD can have significant societal impacts. In addition to below normal temperatures persisting for several days at times, many CAD events are associated with freezing rain and sleet, which can create hazardous travel and aviation delays. For the Southeast United States, the high impact events tend to have a more pronounced jet-entrance region over the Mid-Atlantic region and another jet streak along the Gulf Coast. There is also

Figure 7 Same as Figure 6 except for the hybrid damming events. From Figure 13 in Bailey, C.M., Hartfield, G., Lackmann, G.M., Keeter, K., Sharp, S., 2003. Reprinted with permission.

stronger warm advection and moisture advection off the Atlantic at 850 hPa than drier CAD events. This coupled jet, low-level warm advection, and weaker ridging aloft tend to create relatively strong upward motion forcing aloft and heavy precipitation. Weak CAD has been shown to occur ahead of landfalling tropical systems over the Southeast United States (Floyd, 1999), in which low-level frontogenesis between the CAD and the coastal front can enhance the precipitation well before the landfall of the tropical system.

The CAD region can also create a 'blocking front' within a Rossby radius upstream of the mountain, in which a low-level convergence boundary develops between the terrain-parallel flow and ambient flow approaching the mountain. This boundary has been shown to extend the heavy precipitation upstream of a mountain via this convergence and the flow up and over this blocked region. This has been observed to occur upstream of the Sierras, Wasatch, and European Alps.

Downslope Winds

Introduction

Very strong surface winds sometimes develop when air flows over a high mountain ridge with a steep lee slope. Such winds are known to occur at many locations throughout the middle latitudes. Local names for these winds include the Alpine foehn, the Rocky Mountain chinook, the Croatian bora, the Santa Ana in Southern California, and the Argentine zonda. These winds are collectively referred to as *downslope* winds. Downslope winds in the lee of major mountain barriers can approach hurricane strength. (By definition, hurricanes are storms with *sustained* winds of at least 32 m s^{-1} (115 km h^{-1}).) Every few years, for example, the eastern slope of the Colorado Front Range (part of the Rocky Mountains) experiences a damaging windstorm with peak gusts as high as 60 m s^{-1} (216 km h^{-1}). An anemometer trace recorded at the National Center for Atmospheric Research in Boulder, CO, during a strong chinook is shown in [Figure 1](#).

In modern meteorological usage, downslope winds are distinguished from *katabatic* winds by the dynamical processes driving each flow. Katabatic winds usually refer to shallow gravity currents generated by the cooling of surface air over sloping terrain. Downslope winds usually refer to winds generated as a deeper layer of air is forced over topography. In contrast to katabatic winds, the diabatic cooling of air in contact with a cold surface plays no essential role in the dynamics of downslope winds.

In most downslope wind events (including the typical foehn and chinook), the onset of the downslope wind is

accompanied by an increase in the surface temperature and a drop in the dew point. Whereas the area of violent wind is limited to a relatively narrow swath along and adjacent to the lee slope, the warmer drier air mass can extend much further downstream. Nevertheless, in some cases the upstream conditions may be so cold, and the initial downstream conditions sufficiently warm, that the onset of a downslope wind brings a drop in temperature. The most well-known example of this type of cold downslope wind is the Croatian bora. Despite the difference in the evolution of the surface temperature, there does not appear to be any significant dynamical distinction between the processes responsible for the development of high downslope winds in cold and warm events.

Contours of the potential temperature observed on 11 January 1972 during an intense downslope windstorm are plotted in the vertical cross section through Boulder, CO, shown in [Figure 2](#). These contours provide a rough indication of the streamlines in the flow, which is moving from left to right. (The isentropes would be exactly identical to streamlines if the flow were steady, inviscid, adiabatic, and two-dimensional (2D).) A large-amplitude mountain wave is clearly visible in the potential temperature field just to the lee of the continental divide. The apparent horizontal displacement of the wave trough at upper levels from its position at low levels is due to a 2 h difference between the times at which observations were collected in the upper and lower flight levels. Also apparent in [Figure 2](#) is a layer of enhanced static stability around the 550 mb level in the upstream flow. When intense downslope winds develop in a deep cross-mountain flow, strong mountain waves and low-level stable layers similar to those shown in [Figure 2](#) are usually present.

The connection between mountain waves and strong downslope winds is less apparent in situations where the cross-mountain wind component reverses with height at some level in the middle or lower troposphere, as is often the case in the Croatian bora or when strong winds blow from the east down the western slopes of the Wasatch mountains in Utah. Contours of the potential temperature observed during a moderate bora along a cross section through Senj, Croatia, are shown in [Figure 3](#). The flow in this example is from right to left. A low-level inversion is once again apparent upstream of the mountains; however, no significant wave activity is present above the 3 km level. In this case, the upstream inversion is coincident with a region of strong vertical wind shear in which the cross-mountain wind component reverses direction. The level at which the cross-mountain wind component drops to zero is a critical level for steady 2D mountain waves, and any gravity waves triggered by the mountain break down and dissipate as they approach this critical level. (A critical level is a level at which the phase speed of a wave equals the speed and direction of the basic state flow.)

The Hydraulic Analog

The dynamics governing the development of strong downslope winds in the atmosphere are analogous to those governing the rapid increase in speed that occurs when water flowing over

a rock in a river undergoes a transition from a relatively slow velocity upstream to a thin layer of high-velocity fluid over the downstream face. In such circumstances, a turbulent hydraulic jump often develops downstream of the rock at the point where the high-speed flow decelerates back to the ambient

velocity of the river. Since the fundamental processes responsible for the rapid acceleration of water flowing over a rock can be explained more simply than those which govern downslope winds in the atmosphere, it shall be begun by considering the hydraulic model for a shallow layer of water flowing over an obstacle in an open channel.

Suppose a homogeneous fluid, such as freshwater, is flowing over a ridgelike obstacle. Assuming the flow is steady and that there are no variations in the coordinate direction parallel to the ridge axis, and making the hydrostatic approximation, the flow is governed by the horizontal momentum equation

$$u \frac{\partial u}{\partial x} + g \frac{\partial D}{\partial x} = -g \frac{\partial h}{\partial x} \quad [1]$$

and the mass continuity equation

$$\frac{\partial uD}{\partial x} = 0 \quad [2]$$

where x is the horizontal coordinate directed perpendicular to the ridgeline, u is the velocity in the x direction, D is the thickness of the fluid, and h is the local height of the obstacle. Using eqn [2] to substitute for $\partial u/\partial x$ into eqn [1] yields

$$(1 - F^2) \frac{\partial}{\partial x} (D + h) = \frac{\partial h}{\partial x} \quad [3]$$

Here

$$Fr = \frac{u}{\sqrt{gD}} \quad [4]$$

is the Froude number, which is the ratio of the local flow speed to the local phase speed of a linear shallow water gravity wave.

According to eqn [3], the magnitude of the Froude number determines whether the free surface rises or falls as the fluid ascends the upstream slope of the obstacle. The case $F > 1$, known as *supercritical flow*, is shown in Figure 4(a); the fluid thickens and slows as it passes over the top of the obstacle, and it reaches its minimum speed at the crest. The accelerations experienced by the fluid are qualitatively similar to those experienced by a hockey puck traversing a frictionless ridge of ice. The case $F < 1$, known as *subcritical flow*, is shown in Figure 4(b). The fluid parcel accelerations in the subcritical flow seem counterintuitive in that the fluid thins and accelerates as it crosses the top of the obstacle, reaching its maximum speed at the crest.

Why does a subcritical flow accelerate as it encounters rising bottom topography? In contrast to a frictionless hockey puck, the acceleration of a fluid parcel is determined not only by the gravity and the angle of the slope but also by the pressure gradient forces. The steady-state momentum equation (eqn [1]) requires a three-way balance between acceleration (the first term), pressure gradient forces arising from changes in the fluid depth (the second term), and the work per unit mass done against gravity while ascending the sloping topography (the third term). The value of the Froude number determines whether the work done against gravity is predominantly balanced by accelerations or by the pressure gradient force. From eqn [2]

$$\left(u \frac{\partial u}{\partial x} \right) / \left(g \frac{\partial D}{\partial x} \right) = \left(u \frac{\partial u}{\partial x} \right) / \left(-\frac{gD}{u} \frac{\partial u}{\partial x} \right) = -F^2 \quad [5]$$

Figure 4 Behavior of shallow water flowing over an obstacle: (a) everywhere supercritical flow; (b) everywhere subcritical flow; and (c) hydraulic jump after a transition from subcritical to supercritical flow over the crest. Reproduced from Durran, D.R., 1990. Mountain waves and downslope winds [Figure 4.5]. In: Blumen, W., (Ed.) Atmospheric Process over Complex Terrain. American Meteorological Society, Boston, MA, pp. 59–81.

Thus in steady open-channel hydraulic flow, acceleration always opposes the pressure gradient force due to changes in fluid depth. Furthermore, F^2 may be interpreted as the ratio of the magnitude of the acceleration to the magnitude of the pressure gradient force generated by changes in the fluid depth. In supercritical flow ($F > 1$) acceleration dominates the pressure gradient force and the three-way balance in eqn [1] is satisfied such that fluid parcels ascending the upstream slope decelerate as they do work against gravity.

Before discussing the subcritical case, it is helpful to recast the discussion in terms of the conversions between kinetic energy (KE) and potential energy (PE). Equation [1] implies that $u^2/2 + g(D + h)$ is constant along a streamline. This is just Bernoulli's theorem for steady incompressible hydrostatic flow since the contribution of $w^2/2$ to the total KE is neglected in the hydrostatic approximation. The term $g(D + h)$ represents the combined PEs associated with the gravitational and pressure fields, as may be verified by taking the hydrostatic pressure to be zero at the top of the water and choosing the $z = 0$ level to coincide with the bottom of the channel away from the obstacle; then at an arbitrary level z ,

$$gz + \frac{p}{\rho_0} = gz + g(D + h - z) = g(D + h) \quad [6]$$

According to this generalized interpretation of PE, fluid parcels ascending the obstacle in a supercritical flow slow down as they convert KE into PE, and after passing the crest they reaccelerate as PE is converted back to KE (Figure 4(a)).

On the other hand, in subcritical flow ($F < 1$) the pressure gradient force dominates acceleration and the three-way balance in eqn [1] requires that fluid parcels accelerate in the direction opposite to the component of gravity parallel to the topography. As shown in Figure 4(b), fluid parcels ascending the obstacle accelerate as the free surface drops and PE is converted to KE. After passing the crest, the parcels decelerate as KE is converted back to PE. The disturbance centered over the obstacle in Figure 4(b) is a steady surface gravity wave.

The flow regime that serves as an analog for downslope windstorms is shown in Figure 4(c). If the flow is subcritical upstream and if a column of fluid undergoes a sufficient acceleration and experiences a sufficient decrease in thickness as it ascends toward the crest, a transition from subcritical to supercritical flow occurs at the top of the obstacle. Since the lee-slope flow is now supercritical, fluid parcels continue to accelerate as they descend, and very high velocities can be produced because PE is converted to KE during the entire time over which a fluid parcel traverses the obstacle. The deceleration that would otherwise occur in the lee-side portion of the standing gravity wave is disrupted when the flow becomes supercritical. In this case fluid parcels eventually decelerate when they pass through a turbulent hydraulic jump at some point downstream from the crest.

Application of the Hydraulic Analog to the Atmosphere

The hydraulic analog is best applied to the atmosphere in a qualitative rather than a quantitative manner. Quantitative application is hindered by the difficulty of defining a dynamically meaningful Froude number in vertically unbounded continuously stratified flow. A variety of expressions have been described as Froude numbers in the literature, but all of the simple expressions have serious deficiencies.

The parameter U/Nh_0 , where N is the Brunt–Vaisala frequency, U the wind speed, and h_0 the maximum mountain height, is sometimes referred to as the Froude number in idealized cases in which N and U are constant throughout the upstream flow. Unlike the denominator in the conventional shallow water Froude number, Nh_0 is not the horizontal phase speed of any particularly significant wave. (Nh_0 is the phase speed of a hydrostatic internal gravity wave with vertical wavelength $2\pi h_0$, but there is nothing particularly significant about this wavelength in contrast to other similar waves with wavelengths such as $5h_0$ or $6h_0$.) On the other hand, the maximum perturbation horizontal wind speed u' in linear flow over an obstacle with constant N and U scales like Nh_0 , so that $U/(Nh_0) \approx U/u'$ might be better described as a nonlinearity parameter.

When there is a strong well-defined inversion at some elevation H in the upstream flow, many authors have attempted to define a Froude number as $U/\sqrt{g'H}$, where $g' = g\Delta\theta/\theta_0$ is the 'reduced gravity,' $\Delta\theta$ is the increase in potential temperature across the inversion, and θ_0 is the mean potential temperature below the inversion. The difficulty with this approach is that it implies that the pressure gradient force is entirely determined by the vertical displacements of the inversion layer and thereby neglects the influence, on the surface pressure gradient, of vertical displacements in the stably

stratified fluid above and below the inversion. Moreover, it is also very difficult to determine a precise quantitative value for $U/\sqrt{g'H}$ in more general applications in which the wind speed is not constant below the inversion and the inversion itself may be indistinct. As a consequence, the reduced gravity shallow water model, in which F is replaced by $U/\sqrt{g'H}$ in eqn [3], will not reliably yield reasonable approximations to the speed and depth of the downslope flow in actual windstorms.

Significant downslope winds have been observed to develop in three basic situations: (1) when a standing mountain wave in a deep cross-mountain flow achieves sufficient amplitude to overturn and break down at some level in the troposphere; (2) when standing mountain waves break and dissipate at a critical level in a shallow cross-mountain flow; and (3) when there is sufficient static stability near mountaintop level in the cross-mountain flow to create high downslope winds even without wave breaking. The qualitative application of hydraulic theory to the dynamics of downslope winds centers on the idea that in all three of these cases there is a transition from wavelike behavior over the upstream slopes of the topography to a nonwavelike regime in the lee.

First, consider the case of breaking waves in a deep cross-mountain flow. The structures of the low-level horizontal velocity perturbations in a stationary 2D internal gravity wave forced by an isolated ridge are shown in Figure 5(a). In this case, the upstream wind and static stability are constant with height such that $N = 0.01047 \text{ s}^{-1}$, $U = 10 \text{ m s}^{-1}$, and $Nh_0/U = 0.6$. Streamlines for this same stationary internal gravity wave are plotted in Figure 3(a) (see Mountain Meteorology: Lee Waves and Mountain Waves). As is apparent in Figure 5(a), the detailed structures of the velocity perturbations in the internal gravity wave are somewhat different from those in the surface gravity wave schematically illustrated in Figure 4(b). In particular, the maximum perturbation surface wind speed occurs halfway down the lee slope in the internal gravity wave, whereas it occurs at the crest in the surface gravity wave. Nevertheless, both types of waves allow a fluid parcel to arrive at the ridge crest with a positive perturbation velocity (i.e., to undergo a net acceleration while ascending to the crest), and in both cases the wind speed eventually returns to its ambient value well downstream of the crest as KE is converted back to PE in the lee-side portion of the stationary gravity wave.

The enhancement of the perturbation horizontal winds along the lee slope in Figure 5(a) is too weak to create significant downslope winds. (The total wind speed increases from 10 m s^{-1} far upstream to approximately 15 m s^{-1} in the lee.) Much stronger downslope winds occur in the case shown in Figure 5(b), which is a vertical cross section of the perturbation horizontal velocity in a simulation identical to that shown in Figure 5(a), except that the height of the mountain has been doubled so that $Nh_0/U = 1.2$. The higher topography in this case forces the internal gravity wave to overturn and produces a well-mixed region of weakly reversed flow at elevations around 3 km over the lee slope. (The region of reversed flow is that, in which the horizontal perturbation velocity is less than -10 m s^{-1} .) Streamlines for this same wave-breaking case are shown in Figure 4(a) (see Mountain Meteorology: Lee Waves and Mountain Waves). Although the lee-side flow is dramatically different when the wave is breaking, the flow upstream of the crest remains consistent with that in a stationary internal gravity

Figure 5 Perturbation horizontal velocity in flow over an isolated mountain when (a) $Nh_0/U = 0.6$, contour interval 1 m s^{-1} ; and (b) $Nh_0/U = 1.2$, contour interval 2 m s^{-1} .

wave. Linear theory for stationary internal gravity waves predicts that doubling the mountain height should double the amplitude of the perturbation horizontal velocities without changing the spatial distribution of the perturbations relative to the mountain, and this is essentially the case in the region upstream of the crest. Note, for example, the similarity of the 3 m s^{-1} contour in [Figure 5\(a\)](#) with the 6 m s^{-1} contour in [Figure 5\(b\)](#).

Since the wave in [Figure 5\(b\)](#) has become unstable and overturned above the lee slope, there is no standing gravity wave to decelerate the fluid parcels as they descend. Instead these parcels continue to accelerate as PE is converted to KE along the entire lee slope, generating strong downslope winds in which the maximum surface wind speeds ($>28 \text{ m s}^{-1}$) are approximately three times stronger than the 10 m s^{-1} flow far upstream. Wave breaking in a deep cross-mountain flow appears to have played an important role in the generation of the 11 January 1972 Boulder, CO, windstorm. The presence of breaking waves is suggested by the almost vertical orientation of the isentropes on the lee side of the trough in the upper-level wave in [Figure 2](#) and by the turbulence encountered along the flight legs through this region.

The second type of situation conducive to the development of strong downslope winds is illustrated in [Figure 3](#). In this bora event a critical level at an elevation of about 2 km disrupts the lee-side gravity wave so that, once again, fluid parcels near the surface undergo a net acceleration in the wavelike upstream flow as they ascend the mountain crest and then continue to accelerate as they convert PE to KE while descending the entire lee slope. The vertical displacement of a streamline about its initial undisturbed level $\delta(x, z)$ can be modeled with reasonable fidelity in the flow beneath the critical layer by solving the hydrostatic Long's equation

$$\frac{\partial^2 \delta}{\partial z^2} + \frac{N^2}{U^2} \delta = 0 \quad [7]$$

subject to the lower boundary condition that the streamline follow the topography

$$\delta[x, z = h(x)] = h(x) \quad [8]$$

and an upper boundary condition in which the horizontal wind speed is held constant along a 'dividing streamline'

separating the well-mixed turbulent region from the underlying high-speed flow. In the case shown in [Figure 3](#), the 294 K isentrope approximates a dividing streamline while the 296 K isentrope roughly coincides with the top of the wedge of well-mixed air downwind of the crest. Very close mathematical analogies exist between conventional shallow water hydraulic theory and the mathematical solutions to eqns [7] and [8], although there is no *simple* parameter that plays the role of the Froude number in this analogy.

The third situation that produces strong downslope winds may occur when there is high static stability at low levels in the cross-mountain flow and lower stability aloft. A prototypical example of this type is presented in [Figure 6](#), which shows contours of the perturbation horizontal velocity field and streamlines from a numerical simulation identical to that described in [Figure 5\(a\)](#), except that the Brunt–Väisälä frequency above 3 km in the upstream flow is reduced by a factor of 0.4. Comparison of the horizontal wind speed perturbations between [Figures 5\(a\) and 6\(a\)](#) shows that the perturbation horizontal winds are twice as strong and that the maximum winds have shifted to the surface along the lee slope in the two-layer flow. The amplification of the surface winds in the two-layer simulation is produced without wave breaking; in fact, the flow does not come close to stagnation.

The streamlines within the lower layer shown in [Figure 6\(b\)](#) appear similar to those in water undergoing a transition from subcritical to supercritical flow over the crest of an obstacle. Near the base of the lee slope in [Figure 6](#), the flow recovers toward ambient conditions by radiating energy downstream in a series of vertically trapped gravity waves. The removal of energy by these trapped waves is analogous to the dissipation of energy at the point where the flow recovers toward ambient downstream conditions in a hydraulic jump in the standard shallow water model ([Figure 4\(c\)](#)). Additional sensitivity studies have demonstrated that the changes in the depth of the lower layer and the maximum height of the mountain modify the two-layer flow in a manner one would expect on the basis of hydraulic theory. In particular, making the lower layer too deep or the mountain too small eliminates the transition to a high wind regime.

Figure 6 Two-layer flow over an isolated mountain in which the upstream value of Nh_0/U is 0.6 in the lower layer and 0.24 above: (a) perturbation horizontal velocity contour interval 2 m s^{-1} ; and (b) streamlines within the lower layer.

In actual downslope wind events the dynamical influence of a low-level stable layer may act in concert with wave breaking to generate very high winds. Indeed climatological data and numerical experiments suggest that this is often the case in Boulder windstorms. In particular, nonlinear wave amplification due to the presence of a low-level stable layer appears to have served as a necessary precursor to wave breaking during the 11 January 1972 event.

Introduction

Katabatic winds are a class of atmospheric motion in which air flow is directed down a topographic incline such as a mountainside or glacier. The term 'katabatic' is Greek in origin from katabatikos, meaning to go down, and has been used in meteorological literature since World War I. Reference to katabatic winds is reserved for air motion in the lower atmosphere, extending from the surface to a height typically below 1 km.

In the most general sense, any wind blowing down an incline can be classified as a katabatic wind. The broad definition has allowed a host of local wind features to be defined as katabatic. As air moves downslope, it is subject to adiabatic warming due to compression, since the pressure increases during the descent. Two general categories of downslope winds exist, distinguished from each other by the relative temperature of the air stream. A wind that is warmer than the air being displaced along and at the bottom of an incline is referred to as a 'foehn.' This term has its origin in the warm winds descending the slopes of the Alps in Europe. Similar downslope winds east of the Rocky Mountains of North America have been called 'chinooks', which is taken from the Native American word meaning 'snow eater' to describe the effects of such wind events. The occurrence of these winds requires particular weather conditions in the ambient atmosphere above the downslope flow that directs the air motion.

Use of the term 'katabatic' to describe warm wind features was common throughout much of the early and middle part of the twentieth century, but has decreased over the last few decades. Discussion of katabatic winds now invariably refers to the second type of downslope flow, which is a cold wind. Some air streams originate over high plateaus that are subjected to intense cooling, such as over the interior of the Antarctic or Greenland ice sheets. These air currents remain colder than the surrounding environment during the descent despite compressional heating. Gravity is the driving force for such flows since the density of the cold air is greater than that of the air it displaces. The cold downslope winds are dependent on the local terrain slope characteristics and relative density of the air stream, although weather conditions in the ambient atmosphere are often important as well.

Katabatic winds occur most frequently during nocturnal conditions, and encompass a wide range of time and distance scales. Cold air drainage flows along the sides of valleys having a distance scale on the order of 1 km and the broad continental-scale gravity flows over the great ice sheets of Antarctica and Greenland are each classified as katabatic. The following discussion will focus on the cold, dense downslope wind features for which the term katabatic is most commonly applied.

Dynamics of Katabatic Winds

Topography is the controlling factor for both the intensity and the direction of katabatic winds. This is illustrated schematically in Figure 1, which represents the atmosphere as a simple two-layer fluid. Although highly idealized, the layer model approach in Figure 1 can explain many of the characteristics of katabatic winds. Each layer has a constant density. The lower layer represents the cold, dense layer nearest to the Earth; and the upper layer represents the atmosphere undisturbed by the cooling process. A negatively buoyant lower layer most commonly develops at night when the sky is clear as strong radiative cooling of the inclined surface takes place. Horizontal pressure differences are the fundamental cause for all atmospheric motions. In the case of katabatic winds the horizontal pressure gradient force is proportional to the difference in pressure between the cooled air near the surface (p_1) and at the same horizontal level in the ambient atmosphere overlying the cooled layer (p_2). Through the hydrostatic relationship, the vertical change in pressure is dependent on the air density and the thickness of the air column. For a given height in a vertical column, pressure decreases more rapidly with height for cold air than for warm air. Applying the hydrostatic principle, p_1 will be greater than p_2 if no horizontal pressure difference exists above the cooled layer, and thus horizontal acceleration will occur in a downslope sense. By use of the hydrostatic equation,

Figure 1 Cross-sectional view of two-layer fluid representative of the cold, katabatic wind layer (lower layer) beneath the undisturbed ambient atmosphere; p designates pressure, ρ designates density ($\rho_1 > \rho_2$). H is the height of the katabatic layer above a fixed reference, h is the depth of the katabatic layer above the ground, and z is the terrain height above a fixed reference.

the horizontal pressure gradient (P) in the lower layer can be defined as in eqn [1].

$$P = -g \frac{\Delta \rho}{\rho_1} \frac{\partial H}{\partial s} - \frac{1}{\rho_1} \frac{\partial p}{\partial s_{\text{top}}} \quad [1]$$

In eqn [1], g ($=9.81 \text{ m s}^{-2}$) is the acceleration of gravity, $\Delta \rho$ is the density difference ($\rho_1 - \rho_2$) between the bottom and top layers, ρ_1 is the density in the bottom layer, H is the height of the lower layer above some fixed reference level, and s is a horizontal length scale. Two terms act to force atmospheric motion in the lower layer. The first term represents the effects of cooling over the sloping surface to produce a negatively buoyant air stream. The second term depicts the pressure gradient force in the atmosphere above the lower layer in the horizontal direction along the terrain slope. It is thus evident that the horizontal pressure gradient force in the atmosphere above the cooled layer near the surface is transferred downward through the fluid.

Using the equation of state, eqn [1] may be rewritten in a more convenient form as eqn [2].

$$P = g \frac{\Delta T}{T_1} \frac{\partial H}{\partial s} - \frac{1}{\rho_1} \frac{\partial p}{\partial s_{\text{top}}} \quad [2]$$

Here ΔT is the temperature difference between the two layers ($T_1 - T_2$) and T_1 is the temperature in the bottom layer. In this form, ΔT can be viewed as the strength of the temperature inversion between the cooled layer and the ambient overlying atmosphere. In ordinary atmospheric situations, temperatures decrease with height. Under conditions of a temperature inversion, such as occurs during nocturnal conditions, the coldest air is situated closest to the ground and temperatures increase with height. The strength of the temperature inversion

can be determined from the measurement of temperature in the vertical direction, known as a sounding.

Recognizing that the height H of the density interface is just the sum of the terrain height and thickness of the lower layer, P can also be expressed as in eqn [3], where z is the height of the terrain and h is the depth of the cooled lower layer.

$$P = g \frac{\Delta T}{T_1} \frac{\partial z}{\partial s} + g \frac{\Delta T}{T_1} \frac{\partial h}{\partial s} - \frac{1}{\rho_1} \frac{\partial p}{\partial s_{\text{top}}} \quad [3]$$

The first term in eqn [3] represents the effect of a density contrast over sloping terrain. It can be seen that the size of this term is dependent on the magnitude of the density contrast and the slope of the terrain. This term is sometimes called the buoyancy force. The second term represents the influence of the gradient of thickness of the cooled layer column along the slope. For a situation in which the thickness of the lower layer decreases, as is shown schematically in Figure 1, this term will act to accelerate the downslope component of the flow. For cases in which the horizontal scales are larger than a few kilometers, the second term is generally smaller than the first term and can be neglected. This simplification can also be made if it is assumed that the inversion interface follows the terrain. Both remaining terms, the buoyancy force and the horizontal pressure gradient force in the ambient atmosphere, are important in the forcing of katabatic winds. Although developed for the two-layer model shown in Figure 1, eqn [3] can be applied directly to the atmosphere if potential temperature is substituted for temperature to incorporate the effects of compressibility.

Figure 2 is a nomogram illustrating the relationship between the inversion strength, terrain slope, and ambient pressure gradient. It can be shown that a temperature inversion

Figure 2 Nomogram showing the relationship between inversion strength, terrain slope, and the horizontal pressure gradient force. Extending a straight line between the inversion strength and terrain slope provides a measure of the pressure gradient force associated with katabatic winds. Calculations assume a katabatic layer potential temperature of 273 K; geostrophic wind magnitude is valid at 43° N.

over even gentle slopes can produce significant accelerations. Typical horizontal pressure gradients in the ambient atmosphere are on the order of 100 Pa over a horizontal distance of 100 km, which is equivalent to a geostrophic wind of approximately 8 m s^{-1} in middle latitudes. As can be seen from Figure 2, this is the same magnitude as the buoyancy force arising from a lower layer that is diabatically cooled by 10°C over an incline of approximately 1/500. For steeper inclines with modest temperature inversions, the buoyancy force can be seen to be considerably larger than typical values of the horizontal pressure gradient force in the ambient atmosphere. Because of the large magnitude of the buoyancy force and stable stratification of the atmosphere, katabatic winds respond to the local topographic configuration, often regardless of the pressure gradient in the free atmosphere.

Newton's second law governs the response of a free body to external forces acting on that body. In the case of the Earth's atmosphere, which rotates following the planetary angular velocity, it is advantageous to write Newton's second law in a coordinate system fixed to the Earth. A common method is to express the acceleration of an air parcel in terms of the specific forces (force divided by mass) to form the equation of motion. Atmospheric forces acting to accelerate air include the pressure gradient, gravity, and friction. The Coriolis force is an apparent force arising from the rotation of the Earth. The horizontal vector equation of motion for katabatic flow relative to the rotating Earth can be expressed as eqn [4].

$$\frac{D\mathbf{V}}{Dt} = \mathbf{P} - f\mathbf{k} \times \mathbf{V} + \mathbf{F} \quad [4]$$

Here D/Dt represents the time rate of change following a fluid parcel, $\mathbf{V}$ is the horizontal velocity, t is the time, f is the Coriolis parameter ($2\Omega \sin \varphi$, where Ω is the Earth's angular velocity of $7.29 \times 10^{-5} \text{ rad s}^{-1}$ and φ is the latitude), and $\mathbf{F}$ is the frictional drag. For small horizontal scales of motion of a few kilometers or timescales on the order of a few minutes, the effect of the Earth's rotation is insignificant and acceleration of katabatic flow is subject to the pressure gradient force $\mathbf{P}$ and friction. Under these conditions, the air accelerates directly downslope in the absence of strong forcing from the ambient environment. For larger scales of motion on the order of hundreds of kilometers or timescales on the order of a few hours, the Coriolis force needs to be considered. Acceleration provided by the Coriolis force is directed to the right (left) of the wind vector in the Northern (Southern) Hemisphere. For katabatic winds in which the Earth's rotation cannot be neglected, air streams are deflected across the terrain gradient, often at angles exceeding 45° from downslope. These conditions are found over the great continental ice sheets of Antarctica and Greenland. Observations show that the katabatic wind is deflected at angles across the fall line vector of the terrain that is consistent with effects of the Coriolis force.

Geographical Distribution of Katabatic Winds

Every continent on the Earth experiences katabatic winds. Occurrences are most evident during nocturnal conditions. Along the highlands and slopes of mountainous terrain, rapid

cooling of the surface takes place after sunset during periods of fair weather as the Earth's surface radiates energy that escapes to space. Air in contact with the ground also becomes cooled and hence becomes denser than air at the same horizontal level situated away from the terrain. The cold, dense air then begins to move downslope. Similarly, radiative cooling of air over an elevated plateau, especially one that is covered by snow, results in the development of a pool of cold air, and a shallow dome of high pressure becomes established. Additional accumulation of cold air or passage of extratropical cyclones may act to trigger the release of cold air through mountain gaps or valleys in the form of katabatic winds.

Descriptive names for katabatic wind events have been given to certain episodes that produce profound changes in the local weather or present peril to agricultural or other commercial activities. Nearly, all are the combined result of both cooling of the air stream and the horizontal pressure gradients in the ambient atmosphere. The mistral is a cold, northerly wind that originates in the elevated regions of the Alps, and descends into the Rhone valley and other low-lying regions along the south of France. It is best developed when low pressure forms in the Gulf of Genoa. The cold air often results in frost damage to vineyards. Bora is a name originally used to describe the cold northeast winds observed along the coast of the former Yugoslavia. This air stream originates over Russia and crosses the Carpathian and Alps mountain ranges and descends onto the usually warm shores of the Adriatic Sea. Bora cases are associated with a pressure field consisting of a cyclone near the Black Sea and an anticyclone over the European continent. Both mistral and bora are strong and gusty winds with maximum frequency of occurrence during winter. Other local katabatic winds include the oroshi, a cold wind found on the Pacific side of the mountains on the island of Japan and the coho, a westward surge of cold air off the elevated plateau regions through the Columbia Gorge along the northwest coast of the USA and southern British Columbia. Katabatic winds are not restricted to middle and high latitudes. Cold drainage flows known as *tehuantepecers* occur in the Gulf of Tehuantepec along the Pacific coast of Mexico. Katabatic winds have also been documented in South America along the eastern slopes of the Andes from northern Chile to central Colombia.

Katabatic winds are best developed over the great ice sheets of Antarctica and Greenland. The geographical position of the ice sheets and high reflectivity of the ice fields combine to limit the heating of the surface. Temperature inversions in the lowest 100 m over the elevated interior sections of Antarctica commonly exceed 25°C during nonsummer months. Observations show the surface winds to be consistently of a katabatic nature for much of the year. Surface winds over Antarctic ice slopes are nearly unidirectional, with approximately 90% of the observations from a 30° sector. The katabatic wind systems over Antarctica and Greenland are among the most persistent on the Earth.

To a first approximation, the near-steady flows over the ice sheets can be envisaged as a balance between the horizontal pressure gradient force, the Coriolis force, and the friction force. A simplified but useful approximation for the friction force is $\mathbf{F} = -k\mathbf{V}$, where k is a dimensionless constant having a magnitude between 10^{-2} and 10^{-3} . For steady conditions,

Figure 3 Horizontal view of force balance in the lower atmosphere for katabatic winds over Antarctica; z designates the terrain height, $\mathbf{V}$ is the katabatic wind vector, β is the angle between the wind and the downslope direction of the terrain, P is the horizontal pressure gradient force associated with atmospheric cooling over sloping terrain, C is the Coriolis force, and F is the friction force.

the scalar equations of motion from eqn [4] can be written as eqns [5] and [6].

$$0 = P - fv - \frac{k}{h}Vu \quad [5]$$

$$0 = fu - \frac{k}{h}Vv \quad [6]$$

Equation [5] is the component along the direction of the horizontal pressure gradient force P , which is typically in the downslope direction. Equation [6] is the equation of motion perpendicular to P . Again, V is the magnitude of the wind; $u = V \cos \beta$ and is directed along P ; and $v = V \sin \beta$ and is

directed to the left of and normal to P . The term β is the angle between P and V . The force balance arising from eqns [5] and [6] to produce the steady Antarctic katabatic wind is shown schematically in Figure 3. Equations [5] and [6] can then be solved for V and β (eqn [7]), provided estimates of the strength and depth of the temperature inversion, terrain slope, and pressure gradient force in the ambient environment are known.

$$V = \sqrt{\frac{hP \cos \beta}{k}} = \frac{P}{f} \sin \beta \quad [7]$$

For a given terrain slope, increasing values of P are accompanied by an increase in V and a decrease in β , and hence the flow is faster and directed more downslope. The observed behavior of Antarctic katabatic winds qualitatively matches that prescribed by this simplified model. Assessment of the steady-state wintertime Antarctic katabatic wind regime from eqn [7] is illustrated by streamlines in Figure 4. The force balance between pressure gradient, Coriolis force, and friction results in a katabatic wind vector that is directed across the height contours of the terrain at angles of 30–60° over the interior of the continent. Winds near the coast are directed more downslope. A counterclockwise, divergent katabatic wind pattern is present over the Antarctic ice sheet. A similar pattern can be found over Greenland, except that the motion is in a clockwise sense. By mass continuity, sinking motions must exist over the great ice sheets. A vertical circulation becomes established in the troposphere above the katabatic layer in response to the continental outflow. The strongest winds are found over the steepest ice slopes, which are generally near the coast.

Antarctic katabatic winds are not uniform, as can be seen in Figure 4. Convergence of drainage streamlines is present at various locations about the periphery of Antarctica. Cold,

Figure 4 Streamlines of wintertime katabatic winds over Antarctica. Terrain contours (units of kilometers) of Antarctic ice sheet denoted by thin lines.

negatively buoyant air from a broad horizontal area becomes concentrated into a restricted pathway. These 'confluence zones' represent areas of enhanced cold air supplies available to feed katabatic winds downstream. The most intense and persistent katabatic winds are observed along and downstream of the axes of the confluence zones depicted in [Figure 4](#).

Land and Sea Breezes

RA Pielke, Sr., University of Colorado at Boulder, CO, USA

Synopsis

The physics of land and sea breezes are presented. This includes how they develop in calm conditions and the effect on these mesoscale wind circulations under larger scale wind flow. This article discusses, for example, how light offshore large-scale flow at the coast can amplify the magnitude of low wind convergence associated with a sea breeze, while a stronger wind can prevent the sea breeze from even developing. The reason that the land breeze is a shallower atmospheric feature is presented.

Of all mesoscale phenomena, sea and land breezes have been the most studied, both observationally and theoretically. This is undoubtedly a result of the geographically fixed nature of these phenomena (the location of land–water boundaries) as well as the repetitive nature of the event. The sea breeze is defined as occurring when the wind is onshore, whereas the land breeze occurs when the opposite flow exists. Detailed discussion of sea and land breezes is given in Simpson (1994, 2007), with briefer discussions in Pielke (1984, 2000), Lin (2007), and Atkinson (1981). Sea and land breezes that occur in association with larger lakes are called lake and land breezes (e.g., Neumann and Mahrer, 1975). The leading edge of the sea breeze winds is called the sea breeze front. The first numerical model of the sea breeze was completed by Estoque (1961).

During the case of calm large-scale winds and in flat terrain, it is comparatively easy to describe the diurnal variations of the coastal wind circulations. Defant (1951) presented an excellent qualitative description for this condition, which is illustrated in Figure 1. The idealized sequence of events is as follows:

1. At some time in the early morning, the pressure surfaces become flat and no winds occur (e.g., at 0800 LST – perhaps an hour after sunrise).

2. Later in the morning, mass is mixed upward over land by turbulent mixing in the unstably stratified boundary layer as well as due to the expansion of the volume of air due to its heating, creating an offshore pressure gradient at some distance above the ground (Tijm and van Delden, 1999; Nicholls and Pielke, 1994). Over water, the penetration of sunlight and resultant distribution of radiative heating with depth and the ability of water to mix minimize significant heating of the surface (e.g., at 1100 LST). The temperature of the water is not important in determining the strength of the sea breeze, as long as the air above is warmer than the water.
3. The resultant offshore movement of air above the ground near the coast creates a low-pressure region at the ground, and onshore winds (the sea breeze) develop (e.g., at 1300 LST).
4. The onshore winds transport cooler marine air over the land, thereby advecting the horizontal temperature gradient and, hence, the sea breeze inland. The distance the sea breeze travels inland depends most directly on the intensity of the total heat input to the air (Pearson, 1973; Tijm et al., 1999; Neumann, 1977) and the latitude (Rotunno, 1983) (e.g., at 1600 LST).

Figure 1 Schematic of the diurnal evolution of the sea and land breeze in the absence of synoptic flow. Reproduced from Pielke Sr., R.A., 1984. Mesoscale Meteorological Modeling, second ed. Academic Press, p. 676.

5. As the sun sets, longwave radiational cooling becomes dominant over solar heating, and the local wind field removes the horizontal temperature gradient. The pressure surfaces again become horizontal (e.g., at 1900 LST).
6. As longwave cooling continues and compresses, the air near the ground becomes denser and sinks. The resultant lowering of the pressure surfaces a short distance above the ground creates an onshore wind at that level (e.g., at 2200 LST).
7. In response to the loss of mass above the surface over the water, a pressure minimum develops at the ocean interface immediately off the coast. The offshore wind that then develops near the surface is called the land breeze (e.g., at 0100 LST).
8. The distance of offshore penetration of the land breeze depends on the amount of cooling over the land. Because the planetary boundary layer over land is stably stratified at night and, therefore, vertical mixing is weaker and closer to the ground, the land breeze is a shallower and weaker phenomenon than the daytime sea breeze.

There may even be a third, higher layer of flow associated with these local winds, which Tijm et al. (1999) refer to as a "return–return current."

When the coastline is irregular, local regions of enhanced or weakened low-level convergence develop, as illustrated for the daytime portion of the cycle in Figure 2. (Such zones of preferential convergence help explain the frequency of showers and thunderstorms in certain locations in south Florida during the summer, as seen, for example, in Figure 3 and discussed in Pielke et al., 1991.)

Figure 2 Schematic of the influence of the coastline configuration on a sea breeze in the absence of large-scale flow. Reproduced from Pielke Sr., R.A., 1984. *Mesoscale Meteorological Modeling*, second ed. Academic Press, p. 676.

Figure 3 Radar echo coverage at 1501 EST 19 August 1971 as seen by the Miami WSR-57 10 cm radar. Reproduced from Pielke Sr., R.A., 1974. A three-dimensional numerical model of the sea breezes over south Florida. *Monthly Weather Review* 102, 115–139.

The evolution of the sea breeze is somewhat more complicated when a weak or moderate (i.e., $\lesssim 6 \text{ m s}^{-1}$) prevailing synoptic flow is included. For the two distinct situations of comparatively cold water and comparatively warm water relative to land, a synoptic wind direction from the colder to the warmer surface weakens the intensity of the local wind by diminishing the horizontal temperature gradient. By contrast, when a prevailing larger scale flow of the same strength is from the warmer to the colder surface, if the synoptic wind speed is not too strong, the temperature gradient is strengthened and the subsequent local wind flow is stronger. An example of this effect is shown in Figures 4 and 5, where the sea breeze wind convergence is more clearly evident when the large-scale wind is in the opposing direction from the sea breeze altered flow.

Examples of water that is warm relative to the land include the eastern sides of continents in the tropics and midlatitudes at night and over coastal waters during a polar outbreak. Situations with water that is cold relative to the adjacent land include the eastern sides of continents in the tropics and midlatitudes during sunny days, along the west

side of continents in which upwelling is occurring, as well as along polar coastal areas in the summer. Fog and low stratus often form over the relatively cold water in polar and upwelling ocean areas and move onshore associated with the sea breeze.

The magnitude of the effect of a particular horizontal temperature gradient can be estimated from existing observational and numerical studies. It has been found that, in the tropics and midlatitudes, a horizontal gradient of less than about 10 W m^{-2} per 30 km has only a minor influence on local wind patterns. With a gradient of 100 W m^{-2} per 30 km, however, significant effects are discernible from the statistical evaluation of observational data, whereas at 1000 W m^{-2} per 30 km, the influence on local wind patterns is very pronounced in case-by-case studies. With a nonzero large-scale wind, the heating must be greater in order for a sea breeze to develop. Using observational data, it has been shown that a sea breeze does not develop when the horizontal pressure gradient generated by the differential heating between land and adjacent water is insufficient to overcome the kinetic energy of the large-scale flow.

Figure 5 Same as Figure 4, except for a uniform synoptic southwest wind. Reproduced from Pielke Sr., R.A., 1974. A three-dimensional numerical model of the sea breezes over south Florida. *Monthly Weather Review* 102, 115–139.

When the coastal terrain is hilly or mountainous, sea and land breezes interact with local winds that are created as a result of the heating and cooling of this elevated terrain relative to the adjacent atmosphere at the same altitude. The sea breeze and upslope mountain flows that are created as the terrain is heated during the day, for example, can generate particularly strong onshore winds. However, the subsidence in the adjacent atmosphere caused by the upslope flow can inhibit the development of the sea breeze, resulting in an onshore wind that is less than the sum of the two winds. In addition, the intensity of combined local wind circulation tends to be less when the terrain slope is larger (Segal et al., 1983). Sea and land breezes can result in the accumulation of pollution as air recirculates over industrial and urban areas (Eastman et al., 1995).

Synopsis

Lee Vortices refer to the flow of the atmosphere around mountain barriers resulting in a pair of counterrotating eddies downstream. This article discusses some of the key topographic flow types revealed by laboratory experiments, numerical modeling, and theory.

Introduction

Flow of the atmosphere past a mountain barrier often results in a pair of counterrotating eddies immediately downstream, a flow pattern referred to as *lee vortices*. In some cases, these vortices can be quite persistent, at times lasting for as long as several days. A particularly well-studied example is the island of Hawaii, which often produces stable, quasisteady wakes (Figure 1(a)). However, in other situations, the counterrotating vortex flow turns out to be unstable, and a transition occurs to a state in which vortices of alternating sign are periodically shed downstream. As the eddies drift away, they form a flow structure referred to as a *vortex street*, which is sometimes captured in satellite images. A particularly striking example is shown in Figure 1(b), for flow past an island off the coast of Chile.

Observations show that vortices and wakes are relatively common in mountainous regions, over both the land and the water, and can have important impacts on local weather conditions. Vortices that form near urban areas often influence local air quality, as pollutants are continually recirculated instead of flushing away downstream. Some prominent examples include the Melbourne Eddy (near Melbourne, Australia), the Santa Barbara Eddy (near Santa Barbara, California), and the Denver Cyclone (near Denver, Colorado). Wake eddies have also been linked to the initiation and intensification of severe storms. A well-studied example is the Denver Cyclone, which is often associated with severe

convection, resulting in hail, flooding, and tornadoes. Studies of flow past the Alps suggest that on larger scales, mountain wakes may also play a role in lee cyclogenesis, as the vortices interact with upper level troughs to promote the deepening of synoptic-scale systems.

Lee vortices develop on time scales that are short compared to a day, and have typical length scales on the order of 10–100 km. As a result, in most cases, the rotation of the Earth has only a secondary impact on the motion. Most studies of lee vortices have neglected the role of the Coriolis force (i.e., have considered nonrotating flow), and we adopt the same constraint in the following sections. There is some evidence that for longer temporal and larger spatial scales, the Earth's rotation tends to suppress vortex formation; however, in general, the effect of the Coriolis force on lee vortices has received only modest attention.

Stratified Flow Past Topography: Basic Phenomenology

Overview

Topography can lead to a wide range of flow responses, depending on the background conditions and the size of the barrier. To provide context for our lee-vortex discussion, we first present a brief overview of some of the key topographic flow types, as revealed by theory, numerical modeling, and

Figure 1 (a) Aerial photo of cloud layer in flow past the island of Hawaii. The cores of lee vortices feature warmer air than the surrounding flow, and thus often manifest as holes or breaks in the cloud layer. The lobes of clear air extending downstream of the island in (a) are thus the signature of a pair of counterrotating vortices. Arrows suggest the flow field as inferred from the cloud pattern. (Photo courtesy of Vanda Grubišić.) (b) Satellite image showing a vortex street downstream of Alejandro Selkirk Island, off the coast of Chile. The island is in the bottom left part of the figure.

laboratory experiments. For simplicity (and brevity), we focus on a particular prototype problem: namely, flows past an isolated obstacle, with constant upstream wind U and static stability (or Brunt–Väisälä frequency) N , and without Coriolis effects. While such a simplified model excludes certain, important types of flows (such as trapped lee waves, which depend on changes in N and U), it nonetheless provides a wide range of insights into a variety of real-world disturbances.

We suppose the obstacle shape can be described by a streamwise length scale a , a cross-stream length scale b , and a maximum height h . The key parameters governing the behavior of the flow are then (1) the nondimensional mountain height $\epsilon = Nh/U$, which measures the amplitude (or nonlinearity) of the disturbance; (2) the vertical aspect ratio $\delta = U/Na$, which measures the importance of nonhydrostatic effects; and (3) the horizontal aspect ratio $\beta = b/a$, which measures the effective width of the barrier. In most flows of interest, the vertical aspect ratio δ is relatively small (on the order of 0.1), implying the flow is essentially hydrostatic. For the most part, then, the set of control parameters can be reduced to just ϵ and β .

Laboratory, numerical, and theoretical studies suggest that our simplified prototype problem supports four main classes of flow response: (1) small-amplitude waves; (2) wave overturning and breaking; (3) upstream stagnation and flow-splitting; and (4) lee vortices. The regime diagram in Figure 2 illustrates the occurrence of these phenomena as a function of ϵ and β . Brief overviews of the classes are as follows:

Small-Amplitude Waves

When $\epsilon \ll 1$, the mountain-induced disturbance for all β takes the form of a small-amplitude mountain wave (see **Mountain Meteorology: Lee Waves and Mountain Waves** for examples of small-amplitude waves). The flow in this regime is well described by linear theoretical approaches, which are valid in the limit of small ϵ . As ϵ increases, the streamlines in the wave become more steeply inclined in the vertical, as driven by nonlinear (or finite-amplitude) effects.

Wave Breaking

As long as $\beta \gtrsim 1$ (i.e., for elongated ridges), the streamlines in the wave pattern will steepen to the point of overturning once ϵ

Figure 2 Schematic regime diagram for steady stratified flow past an isolated ridge, as a function of ϵ and β . Note that the actual positions and shapes of the regime boundaries will depend somewhat on obstacle shape.

exceeds some critical value $\epsilon_b(\beta)$, which is usually in the range 0.7–1.2, depending on the obstacle shape. Overturning of the streamlines places more dense fluid over less dense fluid, thus causing the wave to break and become locally turbulent. An example with overturning streamlines and wave breaking is shown Figure 3(a), as seen in a laboratory experiment with $\epsilon = 2.5$ and $\beta = 3$. Wave breaking and the associated turbulence leads to an elevated, well-mixed region above the lee slope, which behaves almost like a free surface, dynamically

Figure 3 (a) Dye lines in the centerline plane for flow past a 3D obstacle with $\epsilon = 2.5$ and $\beta = 3$. The streamline above the lee slope has steepened to the point of overturning, causing the wave to break and the flow to become turbulent. (From Castro, I. P., Snyder, W.H., 1993. Experiments on wave breaking in stratified flow over obstacles. *Journal of Fluid Mechanics* 255, 195–211.) (b) Dye lines in the centerline plane and on the obstacle surface for flow past a ridge with $\epsilon = 2.5$ and $\beta = 2$. The basic flow is from left to right. Flow-splitting is apparent on the windward slope below the second height contour. Also apparent is a wake in the lee, with a hint of possible reversed flow along the centerline. (From Baines, P.G., 1995. *Topographic Effects in Stratified Flows*. Cambridge University Press, 482 pp.) (c) Surface streamlines from a free-slip numerical computation using an obstacle identical to that shown in (b). Note that the dye lines in (b) are suggestive of the streamlines in (c).

decoupling the low-level flow from the flow farther aloft. The flow below the well-mixed region shows a striking similarity to supercritical shallow-water flow, with a rapidly decreasing layer depth and strongly accelerated winds (see **Mountain Meteorology: Downslope Winds** for a discussion of shallow-water flow over a ridge; see also **Dynamical Meteorology: Hydraulic Flow** for a basic discussion of shallow-water dynamics). Downstream of the obstacle, the depressed streamlines abruptly return to their upstream heights, in a structure resembling a shallow-water hydraulic jump (**Figure 3(a)**).

Flow Splitting

Regardless of β , there exists a critical mountain height $\varepsilon_s(\beta)$ at which the flow stagnates on the upstream face of the ridge. The stagnation is caused by the dynamic pressure anomaly in the wave pattern, and occurs at a finite height z_s on the upstream face. Below z_s , the flow splits and passes primarily around the obstacle, instead of over, while above z_s the flow ascends to the peak. **Figure 3(b)** shows an example of upstream stagnation and flow splitting in a laboratory flow, with $\varepsilon = 2.5$ and $\beta = 2$; streamlines from a numerical computation with the same ε and β are shown in **Figure 3(c)**. Flow splitting limits the vertical displacements in the flow, and thus has an inhibitory effect on wave overturning and breaking. For narrow obstacles (i.e., $\beta \leq 1$), splitting is reached at smaller ε than breaking (i.e., $\varepsilon_s < \varepsilon_b$), and breaking is then suppressed for all ε . On the other hand, for elongated obstacles breaking occurs before splitting, and the phenomena are observed to coexist over some range in mountain heights (cf **Figure 2**).

Lee Vortices

A pair of counterrotating vortices appears in the lee of the obstacle whenever ε exceeds some critical value $\varepsilon_c(\beta)$ (**Figure 3(b)** and **3(c)**). In laboratory studies, persistent, counterrotating eddies have been observed only when upstream flow splitting is also present, as in **Figure 3(b)**. However, there is at least some evidence from numerical simulations that for certain flow conditions (particularly for $\beta < 1$), vortices may occur without upstream splitting. In any case, it seems to be true that for most obstacle shapes, splitting, and vortices occur at roughly the same obstacle height, and the two curves are taken to be coincident in **Figure 2**, at least for $\beta > 1$. Vortices with weak flow reversal are likely to be stable and quasisteady. Vortex pairs with more extensive flow reversal are expected to be unstable, and transition to a vortex-shedding state.

Boundary Layers and Free-Slip Models

Consider a laboratory experiment consisting of flow past a stationary topographic obstacle, such as the examples

illustrated in **Figure 3(a)** and **3(b)**. At the exact surface of the obstacle, the fluid is constrained to be motionless, due to frictional coupling with the solid boundary. This assumption is referred to as the *no-slip condition*, and is generally observed to be quite accurate. Immediately above the boundary is a thin shear zone, referred to as a *boundary layer*, above which the flow finally reaches its normal, free-stream speed, as illustrated in **Figure 4(a)**. The depth of the shear zone varies with the strength of the viscosity, but in general the thickness is quite small, much smaller than the size of the obstacle itself. Above the boundary layer, the gradients in the flow are much more gradual, and the associated viscous effects are correspondingly weak.

In the atmosphere, the boundary layer is more complex than that found in a laboratory experiment. Nonetheless, the basic premise of a thin shear zone still applies. For our purposes, we might define the boundary layer thickness to be the depth over which shear effects dominate those of stratification. (In the atmospheric context, this surface shear zone is usually referred to as the *surface layer*, to distinguish it from the deeper *atmospheric boundary layer*, where shear is much weaker.) For a stably stratified atmosphere, this depth is typically on the order of a few tens of meters, much smaller than the types of topographic features associated with lee vortices.

Since the boundary layer is relatively thin, in many cases we can simply ignore it, and assume the flow passes freely along the obstacle surface with no coupling to the boundary below. This approach is referred to as the *free-slip approximation*, and is generally adequate as long as the shear zone remains attached to the obstacle surface. However, in many cases the shear zone does not remain attached, but instead lifts from the obstacle through a process referred to as *boundary-layer separation*. In general, the separation occurs in a region of adverse pressure gradient, where the flow features significant convergence. This convergence causes the layer to be lifted, and ultimately detach from the surface, as illustrated schematically in **Figure 4(b)**. When the boundary layer separates, it carries significant shear vorticity to the fluid interior, and over time, this vorticity can curl into eddies, much like those seen **Figure 1**. Indeed, for many applications (such as flows past cars, airplanes, buildings, etc.), the associated wakes and vortices are entirely due to separating boundary layers.

When lee vortex streets were first captured in satellite images in the early 1960s, it was generally assumed that the vorticity of the eddies was the result of boundary-layer separation. In particular, the cases observed at the time were all found to have strong stable layers below the obstacle crest, which lead to flow splitting on the upstream face of the

Figure 4 (a) Schematic close-up of the boundary layer at the surface of a solid obstacle. (b) Separation of the boundary layer.

obstacle, as in [Figure 3\(b\) and 3\(c\)](#). As the flow passed laterally around the barrier, it was assumed to acquire significant vertically oriented vorticity in the boundary layer, through its coupling with the obstacle surface. Once the boundary layer separated, this vorticity would be shed to the fluid interior, thus leading to eddies circulating about vertical axes.

This boundary-layer explanation remained dominant until the mid-1980s, when simulations of flow past realistic 3D topography first became computationally feasible. One of the early applications of these 3D simulations was a study of flow past the island of Hawaii, as part of the Joint Hawaii Warm Rain Project. Somewhat unexpectedly, the Hawaii researchers soon happened on an interesting discovery: namely, that even when the surface of the island is specified as free-slip, the simulations still produce realistic wakes and vortices, much like those seen in analogous laboratory experiments. As the free-slip condition completely neglects the boundary layer, these simulated vortices are clearly not the result of boundary-layer separation. About the same time, investigators studying other topographic flows found that by decreasing surface friction in their models, they could actually *increase* the strength of the simulated lee eddies. Again, this pointed to something other than the boundary-layer explanation.

Over the past two decades, researchers have mainly focused on processes other than boundary-layer separation as an explanation for lee vortex formation. As explained below, the rotation of the eddies is instead assumed to originate in the fluid interior, either through buoyancy gradients (i.e., baroclinicity), or else through turbulent stresses. In the subsequent sections, we focus mainly on this more recent body of work. That said, it should be kept in mind that for certain flow conditions (most notably, for large δ or for very large ε – say, for $\varepsilon \gtrsim 10$), boundary-layer separation may still play an important role.

Vortex Formation

As with most vortex flows, the process of lee-vortex formation is perhaps best described in terms of the evolution of the vorticity distribution.

Fundamentals

For simplicity, we take the typical lee-vortex flow to be density stratified but essentially incompressible (as is generally the case for most flows of interest). The three-dimensional (3D) vorticity vector $\boldsymbol{\zeta}$ is then governed by

$$\frac{D\boldsymbol{\zeta}}{Dt} = (\boldsymbol{\zeta} \cdot \nabla)\mathbf{u} + \frac{\nabla\rho \times \nabla p}{\rho^2} + \nabla \times \mathbf{F} \quad [1]$$

where $\mathbf{u}$ is the velocity vector, p is the pressure, ρ is the density, and $\mathbf{F}$ represents the effects of viscous or turbulent stresses. The D/Dt notation in [eqn \[1\]](#) indicates a material (or Lagrangian) derivative.

Each of the terms on the right in [eqn \[1\]](#) has a physically distinct impact on the vorticity evolution. The first term is the *stretching and tilting* term, which effectively treats the

vorticity like a small elastic band embedded in the flow. As the flow evolves, the band (and hence the vorticity) is continually deformed by the wind field, with the deformations taking the form of tilting and stretching of the band. The second term on the right is the *baroclinic* term, which describes the rotation generated when a pressure gradient acts on an air mass of variable density. For topographic (and most other) flows, this baroclinic generation is well approximated by

$$\frac{\nabla\rho \times \nabla p}{\rho^2} \approx -\mathbf{k} \times \nabla b \quad [2]$$

where $\mathbf{k}$ is the vertical unit vector and b is the buoyancy. To a good approximation, then, baroclinic generation can be thought of in terms of horizontal buoyancy gradients, and the associated tendency toward vertical motion. The final term in [eqn \[1\]](#) is the *viscous* term, which describes vorticity forcing through viscous and/or turbulent stresses.

Note that according to [eqn \[2\]](#), any vorticity generated through baroclinic effects is strictly horizontal. The development of vertical vorticity thus depends on one of two processes: (a) the direct forcing of vertical vorticity by viscous/turbulent stresses; or else (b) the tilting of horizontal vorticity into the vertical by gradients in the vertical velocity field.

Finally, a full description of the flow requires the first law of thermodynamics, which we can write in the form

$$\frac{D\theta}{Dt} = H \quad [3]$$

where θ is the potential temperature and H is proportional to the diabatic heating. Combining [eqn \[1\]](#) with [eqn \[3\]](#) (and again assuming incompressibility) then leads to the useful conservation relation

$$\frac{DQ}{Dt} = \boldsymbol{\zeta} \cdot \nabla H + (\nabla \times \mathbf{F}) \cdot \nabla \theta \quad [4]$$

where $Q = \boldsymbol{\zeta} \cdot \nabla \theta$ is the *potential vorticity* (the potential vorticity is usually defined as $\Pi = \boldsymbol{\zeta} \cdot \nabla \theta / \rho$, where ρ is the density. By this standard definition, $Q = \rho \Pi$ is then the potential vorticity per unit volume, in the same sense that ρu is the x momentum per unit volume. As this is cumbersome terminology, we refer to Q simply as the potential vorticity) (see **Dynamical Meteorology: Potential Vorticity**).

According to [eqn \[4\]](#), for flow which is both adiabatic ($H = 0$) and inviscid ($\mathbf{F} = 0$), the potential vorticity maintains a constant value along particle trajectories. In the particular case in which the upstream potential vorticity is zero (as in the example below), this further implies that the vorticity vector must remain tangent to isentropic surfaces (or surfaces of constant θ), at least until the onset of dissipative processes.

Vertical Vorticity

Much of the analysis of lee vortices has been based on idealized modeling experiments, such as that shown in [Figures 5 and 6](#). In the example shown, the flow consists of a uniform wind started impulsively from rest at time $t = 0$ (much as in a towing tank experiment). The upstream static stability is roughly analogous to a trade-wind flow, with an inversion layer extending from $h/2$ to $0.7 h$ (with $N = 0.02$), with weaker

Figure 5 Early evolution for a stratified numerical simulation with flow accelerated rapidly from rest (from left to right), with an inversion layer below obstacle crest. (See text for details.) Shown is an isentropic surface near the base of the inversion, with the coloring of the surface indicating buoyancy (red colors positive, blue colors negative). The red and purple tubes show selected vortex lines running roughly parallel to the θ -surface, with the coloring of the lines indicating the direction of the vorticity. Red lines circle the obstacle in a clockwise sense, and purple lines counterclockwise. Vectors show the flow field at the ground. Times shown include (a) $Ut/L = 0.25$ and (b) $Ut/L = 1.00$, where U is the background wind and L is the obstacle half-width. (c) Same as (b), but from an alternate viewing angle that highlights the tilting of the vortex lines.

stability aloft ($N = 0.005$) and below ($N = 0.01$). Both the initial and upstream states have zero vorticity and thus satisfy $Q = 0$.

Figure 5 shows the early stages of evolution for the experiment described above, which highlights the development of circulation about a vertical axis. Shown in the figure is an isentropic surface near the base of the inversion layer, along with the buoyancy and vortex lines (a vortex line is a curve in space along which the vorticity vector is everywhere tangent. Vortex lines are thus to the vorticity field what streamlines are to the velocity) on the isentropic surface and

the velocity vectors at the ground (see the figure caption for details). Note that for ease of interpretation, the vertical scale of the figure has been exaggerated by a factor of roughly seven: in reality, the height of the obstacle is significantly less than its width.

For the early development shown in Figure 5, the basic flow structures can be described reasonably well in terms of Taylor series in time – specifically, by expanding eqns [1] and [3] as Taylor series about $t = 0$, and then grouping terms of like order in Δt . While the details of the expansion are somewhat involved, the end results suggest the following stages of development:

1. At $O(\Delta t)$, the main event is the production of buoyancy anomalies. Specifically, the ascending flow on the upstream face of the obstacle leads to negative buoyancy, while positive buoyancy is produced in the lee.
2. Once buoyancy anomalies exist, the vorticity follows through the baroclinicity term eqn [2]. The pattern of vorticity (as determined by the cross product) takes the form of two sets of loops: a set of clockwise loops on the upstream side, and a set of counterclockwise loops downstream (Figure 5(a)). The interface between the two sets is found roughly parallel to the ridgeline (at $x = 0$). At this stage, the vorticity is strictly horizontal.
3. With time, the pattern of vorticity loops is advected downstream, so that the interface between the clockwise and counterclockwise loops is found along the lee slope (Figure 5(b)).
4. Eventually (technically at $O((\Delta t)^4)$), as the vorticity pattern shifts downstream, the vorticity loops are tilted downward along the edges by the descending flow over the lee slope, thus producing vertical vorticity (Figure 5(b) and 5(c)). The sense of the tilting is to produce positive vertical vorticity on the right side of the flow (facing downstream) and negative on the left.

At the early stages shown in Figure 5, the developing flow is roughly adiabatic and inviscid, suggesting that vortex lines remain embedded in isentropic surfaces. Thus, as the θ -surface is dragged downward by the descending flow, the vortex lines on the surface are dragged downward as well. As seen below, these regions of tilting and vertical vorticity production later become the centers of the developing vortex.

Evolution and Reconnection

The subsequent evolution of the flow to the point of fully formed vortices is illustrated in Figure 6. As seen in the figure, the flow downstream of the obstacle quickly reaches a state of stagnation, which halts the downstream progression of the isentropic surface along the ground (Figures 5(b) and 6(a)). However, at the wake edges the flow remains accelerated, and the resulting shear zone then tends to deform the isentropic surface along either side, as illustrated in Figure 6(a)–6(c). This deformation of the θ -surface implies significant lateral buoyancy gradients at the wake edges, which ultimately causes the air in the wake region to spread laterally (Figure 6(c)). In time, the spreading wake air reconnects with the air outside the wake

Figure 6 Same as [Figure 5](#), but for $Ut/L =$ (a) 1.5, (b) 2.75, (c) 4.0, (d) 5.5. After Epifanio, C.C., Rotunno, R., 2005. The dynamics of orographic wake formation in flows with upstream blocking. *Journal of Atmospheric Science* 62, 3127–3150.

([Figure 6\(d\)](#)), and the flow reaches its mature state, with a pair of fully recirculating lee eddies.

Interestingly, the reconnection of the flow as seen in [Figure 6\(d\)](#) has the effect of pinching off a hole in the θ -surface at the vortex center. Since the air above the inversion is warmer and (typically) drier than the air below, this pinched off area often shows up as a hole in the cloud layer in satellite images, as seen in [Figure 1\(b\)](#).

The Retracting Piston

[Figure 7](#) shows the flow evolution in the obstacle's centerline plane ($y = 0$), which highlights the development of reversed flow. For the purposes of illustration, the flow is shown in a reference frame that moves with the background wind – that is, in the reference frame of the figure, the background state is seen to be at rest, while the obstacle moves through the fluid (much as in a towing-tank experiment).

As the obstacle is set in motion, the air upstream of the obstacle below the inversion layer quickly becomes blocked ([Figure 7\(b\)–7\(d\)](#)), which allows warmer air from aloft to descend the lee slope. This descending air from above sets up a strong temperature contrast with the air downstream, which quickly collapses to form a lee-side front (or hydraulic jump-like structure), as seen in [Figure 7\(b\)–7\(d\)](#). The strong baroclinicity across the front leads to a plume of positive (i.e., into the plane of the figure) vorticity in the inversion layer downstream, which in turn implies a current in the upstream direction in the air below the inversion. As the topography is pulled away, the air below the inversion thus propagates into the space vacated by the obstacle, much as a density current would propagate into warmer air. As seen from the ground-based frame, this lee-side propagation appears as a deceleration and eventual reversal of the lee-side flow.

The flow development shown [Figure 7](#) has a close analog in the theory of shallow-water fluids, in which a piston at one end of a container of fluid is abruptly pulled away from the fluid at $t = 0$. As the piston retracts, the fluid adjusts under gravity so as to flow into the space vacated by the piston, much as the colder air downstream flows into the space vacated by the obstacle in [Figure 7](#). Interestingly, the same type of evolution (including flow reversal) occurs even in flows past 2D topography – that is, with respect to flow reversal, at least, the dynamics of wake formation is not inherently 3D.

Potential Vorticity Dynamics

A different but complementary view of lee vortices follows from a consideration of dissipative effects in the flow. As suggested by [eqn \[4\]](#), a key impact of dissipative processes is the production of potential vorticity (PV) anomalies.

The PV-Bernoulli Relation

The PV relation [eqn \[4\]](#) is often usefully considered in its equivalent conservation-flux form

$$\frac{\partial Q}{\partial t} = -\nabla \cdot \mathbf{J} \quad [5]$$

where

$$\mathbf{J} = \mathbf{u}Q - \zeta\mathbf{H} + \nabla\theta \times \mathbf{F} \quad [6]$$

is referred to as the flux of PV. According to [eqn \[5\]](#), PV is created locally wherever the PV flux [eqn \[6\]](#) is convergent or divergent. The PV flux $\mathbf{J}$ can in turn be divided into two parts: an advective part $\mathbf{u}Q$ which describes the transport of PV by the

Figure 7 Flow in the centerline plane of the obstacle for the numerical simulation in [Figures 5 and 6](#). Fields are shown in a reference frame moving with the background wind, so that the obstacle appears to move leftward. Shown are the vorticity in the plane of the figure (red colors into the page, blue out of the page) and the velocity vectors in the figure's frame of reference. Black contours show isentropic surfaces at roughly the top and bottom of the inversion layer. Shown are times spanning $0 \leq Ut/L \leq 2.1$, with a time interval of $Ut/L = 0.7$. After Epifanio, C.C., Rotunno, R., 2005. The dynamics of orographic wake formation in flows with upstream blocking. *Journal of Atmospheric Science* 62, 3127–3150.

wind, and a dissipative part, whose convergence is the Lagrangian tendency in [eqn \[4\]](#).

In the case of lee vortices, the PV flux is often described in terms of its relation to the Bernoulli function

$$B = \frac{\mathbf{u} \cdot \mathbf{u}}{2} + c_p T + gz \quad [7]$$

where T is the sensible temperature, c_p is the specific heat at constant pressure, and g is the gravitational constant (see

Bernoulli Function). The Bernoulli function satisfies its own conservation relation, specifically

$$\frac{DB}{Dt} = \mathcal{J} + \mathbf{u} \cdot \mathbf{F} + \frac{1}{\rho} \frac{\partial p}{\partial t} \quad [8]$$

where $\mathcal{J} = c_p TH/\theta$ is the diabetic heat source. If the flow is steady, then the Bernoulli function remains constant along streamlines, except where acted upon by dissipation (much like the PV).

For the case of steady-state flow, it can be shown that the Bernoulli function ([eqn \[7\]](#)) and the PV flux ([eqn \[6\]](#)) are related by the simple expression

$$\mathbf{J} = \nabla \theta \times \nabla B \quad [9]$$

implying that PV generation is closely tied to the production of Bernoulli anomalies. According to [eqn \[9\]](#), at steady state the PV flux is tangent to both isentropic surfaces and surfaces of constant B . Typically, the flux is visualized on isentropic surfaces, in which case the flux vector is tangent to contours of B on the surface.

PV Generation in Wakes

The close relationship between PV fluxes and Bernoulli anomalies in orographic wakes is illustrated in [Figure 8](#). Shown in the figure are schematics of flows on an isentropic surface at steady state. In the case of [Figure 8\(a\)](#), the flow passes directly over the obstacle, with no blocking, and encounters a dissipative zone over the lee slope, presumably due to wave breaking. For [Figure 8\(b\)](#), the flow is blocked upstream and passes laterally around the obstacle, with the isentrope intersecting the terrain, and with a recirculation zone in the lee. In both cases the upstream flow has zero PV and constant B , so that any anomalies downstream are due entirely to dissipation over the obstacle.

In the case with wave breaking ([Figure 8\(a\)](#)), the dissipation in the breaking zone typically causes a reduction in the Bernoulli function for particles passing through the dissipative area. These reduced Bernoulli values are then carried away downstream, leading to a wake of reduced B , as shown in the figure. In terms of PV, the Bernoulli gradient across the breaking zone implies a PV flux from left to right (facing downstream), which according to [eqn \[6\]](#) must be mainly due to the dissipative parts of $\mathbf{J}$ (since the flux is perpendicular to $\mathbf{u}$). At the edges of the wake, the Bernoulli gradients imply PV fluxes downstream, with a positive (downstream) flux on the right and a negative (upstream) flux on the left. Since the flow downstream is largely nondissipative, these fluxes must be primarily due to the $\mathbf{uQ}$ term in [eqn \[6\]](#). Overall, then, the conceptual model is one of PV anomalies being created at either edge of the breaking zone through dissipation and then being advected away downstream, with positive PV on the right and negative on the left. In between the PV anomalies is a wake of decelerated air, with reduced values of Bernoulli function.

[Figure 8\(b\)](#) shows a slightly more subtle case, in which the flow on the upstream face of the obstacle is blocked, causing the θ -surface to intersect the terrain (as in the examples from the previous section). Downstream of the obstacle is a pair of recirculating eddies, with reduced Bernoulli function in the recirculation zones. As in the breaking case, the Bernoulli gradients at the wake edges imply fluxes of PV, with a positive (downstream) flux on the right side and negative (upstream)

Figure 8 Schematic illustration showing PV generation in stratified flow past an obstacle. Shown are flow fields as visualized on an isentropic surface, with solid contours indicating streamlines. In (a), the isentropic surface completely covers the terrain with no blocking, while (b) shows a case with blocking on the upstream face, causing the isentropic surface to split. The hatched area in (a) is a region of turbulent wave breaking, while dark shading in (b) shows a hole in the isentropic surface, where the surface intersects the obstacle. For both panels, the shaded area downstream is a region of reduced Bernoulli function in the wake. Open arrows show the PV flux $\mathbf{J}$ associated with the Bernoulli gradient on the isentropic surface. From Schär, C., Durran, D.R., 1997. Vortex formation and vortex shedding in continuously stratified flows past isolated topography. *Journal of Atmospheric Science* 54, 534–554.

flux on the left. However, unlike the breaking case, the PV fluxes in the blocked flow are thought to be associated with reconnection, rather than breaking. Specifically, as air in the wake eddies recirculates, it eventually joins with air from outside the wake at the wake edges, thus bringing low-Bernoulli air in contact with air whose Bernoulli function remains constant at the upstream value. The resulting Bernoulli gradient implies a downstream PV transfer, with positive PV on the right and negative on the left.

Note that as presented, the cause of the Bernoulli reduction in **Figure 8(b)** is not immediately apparent. Regardless, the Bernoulli drop must be tied to dissipation in some form: the most likely causes are either dissipation in jump-like or wave-breaking features along the lee slopes (or perhaps the flanks) of the obstacle, or else weak diffusion distributed throughout the entire wake zone.

PV Banners

Orographic PV anomalies were studied as part of the Mesoscale Alpine Programme, a large international field campaign conducted during the fall of 1999. **Figure 9** shows two examples: one for flow past the Alps (**Figure 9(a) and 9(c)**) and one for the Dinaric Alps (**Figure 9(b) and 9(d)**). In both cases, the wake flow was analyzed using a variety of tools, including instrumented aircraft, dropsondes, and mesoscale model results.

As illustrated in **Figure 9(a) and 9(b)**, topographically generated PV anomalies often take the form of long, narrow plumes extending downwind of the terrain. In general, these plumes occur as positive-negative couplets, with each couplet tied to a specific feature in the terrain profile. As illustrated by the figure, a complex mountain range such as the Alps or Dinaric Alps can lead to a number of PV anomalies being generated simultaneously. In the case of the Alps (**Figure 9(a) and 9(c)**), the individual anomalies associated with specific peaks are further embedded within a larger overall PV couplet, associated with the mountain range as a whole. (Indeed,

Figure 9(c) shows just the positive branch of this larger overall couplet.)

Given their visual appearance, PV anomalies such as those shown in **Figure 9** are often referred to as *PV banners*, suggesting an analogy to pennants attached the mountain peaks. As seen along flight tracks (as in **Figure 9(d)**), these PV banners often take the form of oscillations, with crests and troughs of PV where the various PV couplets cross the track. The cross-stream dimensions of the banners appear to vary somewhat: in **Figure 9**, the smaller individual banners have widths of 10–20 km, while the larger Alps-scale banner has a scale closer to 100 km. As seen in **Figure 9(c)**, the PV tends to be limited to levels below the mountain peaks, with the strongest anomalies in the inversions at the top of the boundary layer. That said, it is reasonable to expect (but not yet shown) that similar anomalies might occur at higher altitudes, associated with breaking waves.

Results from model simulations suggest that PV banners often extend far downstream, at least as far as several 100 km. (For the particular case of Hawaii, traces of the wake can be discerned in satellite observations at incredible distances, perhaps as much as 3000 km downstream. The details of this extremely long wake remain uncertain: one possibility is that air–sea interaction plays a role.) In some cases the individual plumes associated with specific peaks appear to coalesce downstream, leading to larger vortices on the scale of the entire mountain range. For the case of the Alps, these larger vortices are then large enough to affect synoptic-scale flows, perhaps leading to enhanced lee-side cyclogenesis (see **Mountain Meteorology: Orographic Effects: Lee Cyclogenesis**).

Shallow-Water Wakes

The vortices described above for stratified flows have close analogs in shallow-water dynamics as well. **Figure 10** shows two examples: one in which the fluid layer passes completely over the obstacle (**Figure 10(a) and 10(b)**), and one in which

Figure 9 Orographic PV anomalies as observed during the Mesoscale Alpine Programme. (a) Flow past the Alps as computed by the MC2 model with 3-km horizontal resolution. Shown are the wind vectors and PV anomalies (solid contours/dark shading shows positive values, dashed contours/light shading shows negative) as seen on the 850 hPa pressure surface. Thick solid contour shows the intersection of the pressure surface with the terrain. (b) Cross section along the contour indicated in (a) (A to B), showing objectively analyzed fields from both aircraft and dropsonde data. Shown are PV (PVU; shaded with colorbar) and potential temperature (contours). Adapted from Schär, C., Sprenger, M., Lüthi, D., Jiang, Q., Smith, R.B., Benoit, R., 2003. Structure and dynamics of an Alpine potential-vorticity banner. *Quarterly Journal of the Royal Meteorological Society* 129, 825–855. (c) Flow past the Dinaric Alps, as computed by the COAMPS model at 3-km horizontal grid spacing. Shown are PV (solid contours positive, dotted negative) and wind vectors at a height of 600 m above sea level. Shaded areas indicate terrain features higher than 600 m. (d) PV along the contour indicated in (c) (A to B) as computed from aircraft flight level data (thick solid). Also shown are PV anomalies computed by the COAMPS model, at times bracketing the aircraft observations (dashed and dotted). the flow is blocked upstream, causing the layer to split around the obstacle (**Figure 10(c) and 10(d)**).

In the case shown in **Figure 10(a) and 10(b)**, the flow becomes supercritical as it passes over the obstacle peak, with rapidly decreasing layer depth and strongly accelerated flow along the lee slope (not shown). At the base of the obstacle, the depth abruptly recovers to nearly its upstream value in a hydraulic jump (indicated by the bold solid line), much like that seen in **Figure 3(a)**. Downstream of the jump is a pair of recirculating eddies, with plumes of vertical vorticity extending downstream along the wake edges (**Figure 10(b)**).

Hydraulic jumps are inherently dissipative features, and are thus at least broadly similar to the wave-breaking region shown

in **Figure 8(a)**. As seen in **Figure 10(b)**, the flow entering the jump acquires the shallow-water equivalent of PV, which then streams away downstream along the edges of the wake as a pair of PV banners. The jump also produces a loss in Bernoulli function, resulting in a Bernoulli deficit in the wake zone. As in the stratified case, this Bernoulli loss and the PV generation are closely related, with direct analogs to eqns [5], [6], and [9] applying at steady state.

In the case shown in **Figure 10(c) and 10(d)**, the obstacle is sufficiently large that the fluid layer is unable to ascend to the peak, thus splitting on the upstream face and passing around the sides. In the lee of the obstacle is a pair of recirculating eddies. As in **Figure 8(b)**, a pair of PV anomalies emanate from

Figure 10 Lee vortices in free-slip shallow-water flow. Shown are (a) streamlines and (b) vorticity for a case in which the fluid layer completely covers the obstacle, with supercritical flow along the lee slope. (c) and (d) as in (a) and (b), but for a case in which the obstacle pierces the fluid surface, causing the flow to split on the upstream face. Heavy solid lines in all panels show the positions of hydraulic jumps. The blank region in (c) shows the part of the obstacle above water level. Modified from Schär, C., Smith, R.B., 1993. Shallow-water flow past isolated topography. Part I: Vorticity production and wake formation. *Journal of Atmospheric Science* 50, 1373–1400.

the flanks of the obstacle, where recirculating wake air joins with air passing laterally around the barrier. The flow also features a pair of weak hydraulic jumps just upstream of the reconnection points (often referred to as *flank shocks*), which are absent in Figure 8. Nonetheless, observations of flow past Hawaii suggest that similar jump-like or wave-breaking features may in fact exist in the real world.

The time shown in Figure 10(c) and 10(d) is a time when the wake has already reached a mature and quasisteady state. However, consideration of the earlier transient evolution reveals strong similarities to the example case shown above (in the Vortex Formation section), including a retracting piston response like that shown in Figure 7, and a recirculation and reconnection phase much like that in Figure 6. The flow even features a hole in the fluid layer at the vortex center, much like the hole in the isentropic surface shown in Figure 6(d).

Vortex Shedding

The previous sections describe wakes that are essentially symmetric, with a pair of attached, counterrotating vortices. However, in many cases, wakes transition to a completely different state, in which vortices are continually shed downstream, with each successive shed vortex having opposite

rotation from the last. The resulting *vortex streets* can lead to striking satellite images, such as that shown in Figure 1(b).

Vortex streets are thought to result from a pair of attached (i.e., nonshedding) vortices that becomes unstable. The instability initially manifests as an oscillation, with each eddy in the vortex pair becoming alternately stronger and weaker. However, as the oscillation grows, the eddies eventually begin to detach and drift downstream, thus transitioning to a vortex shedding state. The instability that drives this transition is effectively a property of the shear flow in the counterrotating eddies, and thus has little dependence on either the mechanism of vortex formation or the details of the flow near the obstacle. As a result, the dynamics of shedding in geophysical wakes is surprisingly similar to that found in homogenous wakes, for which there is an extensive literature.

Figure 11 shows the instability and transition to shedding for an elongated shallow-water wake, with the attached, symmetric state of the wake shown in Figure 11(a) and 11(b). The flow in Figure 11(a) and 11(b) supports two different types of instability modes. The first is a local mode that grows along the shear lines at the wake edges, and which behaves roughly like a classic inflection-point instability. However, the energy of this instability propagates rapidly away downstream, before the disturbance has a chance to grow substantially.

Figure 11 Wake instability and vortex shedding in shallow-water flow. The flow shown in (a) and (b) consists of a perfectly symmetric, counterrotating, stable wake, as computed numerically using an enforced symmetry condition. The symmetry condition is then removed (at time $t = 0$), which allows the growth of nonsymmetric instability modes, as illustrated in (c) and (d). Shown are the (a) streamlines and (b)–(d) vorticity at times (a), (b) $t = 0$, (c) $(gD)^{1/2}t/a = 36$, and (d) $(gD)^{1/2}t/a = 72$, where a is the obstacle half-width and D is the upstream fluid depth. Adapted from Schär, C., Smith, R.B., 1993. Shallow-water flow past isolated topography. Part II: Transition to Vortex Shedding. *Journal of Atmospheric Science* 50, 1401–1412.

The second type of instability is an antisymmetric, global oscillation, which involves coupling of the two shear lines with the reversed flow in between. Modes of this type grow in place, and are thus able to significantly disrupt the wake pattern.

As seen in **Figure 11(c)**, the instability first manifests as a wavelike oscillation near the downstream stagnation point. As the oscillation grows, the flow begins to shed isolated vorticity patches (**Figure 11(d)**), predominately from the downstream edge of the wake. Eventually the instability works its way back to the lee slope, and complete, recirculating vortices of alternating sign are shed from either side of the obstacle, with nearly perfect periodicity (not shown).

Detailed analysis shows that the growing oscillation tends to emanate from the parts of the wake with flow reversal. Wakes without reversed flow are thus expected to be stable. Similarly, if the wake features only a limited region of weak reversed flow, then the dispersion of energy away from this region may be sufficient to suppress the growth of the mode. The transition (or bifurcation) point between weak, stable wakes and stronger, unstable wakes has yet to be explored in much detail for shallow-water flow. However, it seems likely that for the free-slip and inviscid case, at least, virtually any wake with flow reversal will eventually become unstable, as the wake elongates downstream.

Simulations including viscosity and bottom friction show that both processes tend to exert a stabilizing influence, particularly for wakes with only weak flow reversal. The source of the stabilization is primarily a decrease in the length of the wake (thus reducing the extent of the reversed flow), and to a lesser degree the damping of the instability modes themselves. Of the two damping processes, it appears that bottom friction in particular is likely an important stabilizing factor in the real atmosphere. This presumably accounts for the many apparently stable vortices observed in real-world flows, such as the case of Hawaii shown in **Figure 1(a)**.

Lee Waves and Mountain Waves

DR Durran, University of Washington, Seattle, WA, USA

Synopsis

The basic properties of mountain waves are discussed using linear theory for small-amplitude disturbances. Important nonlinear processes governing waves launched by larger mountains are then considered. The final topic is mountain-wave momentum flux and the interaction of these waves with the larger-scale flow.

Introduction

Buoyancy perturbations develop when stably stratified air ascends a mountain barrier. These perturbations often trigger disturbances that propagate away from the mountain as gravity (or buoyancy) waves. Gravity waves triggered by the flow over a mountain are referred to as 'mountain waves' or 'lee waves.' Mountain waves sometimes reveal their presence through dramatic cloud formations, such as smooth lenticular

Figure 1 Single lenticular cloud over Laguna Verde, Bolivia. This cloud was probably formed by a vertically propagating mountain wave. Copyright Bernhard Mühr, www.wolkenatlas.de.

Figure 2 Multiple lenticular clouds over Mývatn, Iceland, formed by trapped lee waves. Copyright Georg Müller, www.wolkenatlas.de.

clouds (see [Figures 1](#) and [2](#)) and ragged rotor clouds. Large-amplitude mountain waves can generate regions of clear air turbulence that pose a hazard to aviation. Large-amplitude mountain waves may also produce very strong winds that blow down the lee slope of ridgeline topographic barriers (see **Mountain Meteorology: Downslope Winds**).

What happens to mountain waves after they are generated? If the wave amplitude becomes large in comparison to the vertical wavelength, the streamlines in a vertically propagating mountain wave steepen and overturn in a manner roughly analogous to a breaking wave in the ocean. Such 'convective' overturning often occurs as the waves enter the lower stratosphere where they encounter increased static stability and decreasing horizontal wind speeds. The convective overturning of vertically propagating waves is also promoted by the systematic decrease in atmospheric density with height. Those waves that do not breakdown due to convective overturning before reaching the mesosphere are ultimately dissipated by the vertical transfer of infrared radiation between the warm and cool regions within the wave and the surrounding atmosphere (radiative damping).

Horizontal momentum is transported by mountain waves from the regions of wave dissipation to the surface where a net pressure force is exerted on the topography. A decelerative force is exerted on the large-scale atmospheric circulation in those regions where the wave undergoes dissipation.

The basic structure of a mountain wave is determined by the size and shape of the mountain and by the vertical profiles of temperature, wind speed, and moisture in the impinging flow. The overall character of the wave can often be predicted on the basis of linear theory, in which the mountain is assumed to be small in comparison with the vertical wavelength of the mountain wave, and such theory will be the subject of the next section. Nevertheless, nonlinear effects do exert a significant influence on the wave amplitude and are essential to the dynamics of mountain-wave dissipation in regions of wave breaking; such effects will be considered later in this article.

Linear Mountain-Wave Theory

The strongest mountain waves are forced by long quasi-two-dimensional ridges that are sufficiently narrow so that the dynamical influence of the Coriolis force can be neglected. The

basic dynamics of these waves are largely captured by the linear theory for steady two-dimensional Boussinesq flow over an obstacle, for which the linearized momentum, thermodynamic, and continuity equations may be reduced to the following single equation for the vertical velocity w ,

$$\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial z^2} + \ell^2 w = 0. \quad [1]$$

Here x is the horizontal coordinate perpendicular to the ridge-line; z is the vertical coordinate, and

$$\ell^2 = \frac{N^2}{U^2} - \frac{1}{U} \frac{d^2 U}{dz^2} \quad [2]$$

is the 'Scorer parameter' in which $U(z)$ is the speed of the basic-state flow and $N(z)$ is the Brunt-Väisälä frequency (or alternatively, the buoyancy frequency). In the Boussinesq limit, the Brunt-Väisälä frequency may be defined in terms of the basic-state potential temperature $\bar{\theta}(z)$, a constant reference potential temperature θ_0 , and the gravitational acceleration g , such that $N^2 = (g/\theta_0) d\bar{\theta}/dz$.

Neglecting the effects of surface friction, the velocity perpendicular to the topography must vanish at the surface of the topography $z = h(x)$. This constraint provides a lower boundary condition for eqn [1], and can be approximated as $w(x, 0) = U \partial h / \partial x$ to the same order of accuracy retained in the linearized governing equations. The atmosphere has no distinct upper boundary, so the upper boundary condition is imposed in the limit $z \rightarrow \infty$. In order to ensure the physical relevance of mathematical solutions to eqn [1] in the infinitely deep atmosphere, those solutions must satisfy one of the two possible conditions, that is, either (i) the perturbation energy density must approach zero as $z \rightarrow \infty$, or (ii) if the perturbation energy density is finite as $z \rightarrow \infty$, then the perturbation energy flux associated with each individual's vertically propagating mode must be upward. The second condition allows the representation of disturbances generated within the domain that propagate energy upward to arbitrarily great heights, but it prohibits downward propagating modes from radiating energy into the domain from infinity.

Constant Wind Speed and Stability, Sinusoidal Ridges

As a first example consider flow in a horizontally periodic domain in which $h(x) = h_0 \sin(kx)$. The lower boundary condition becomes $w(x, 0) = U h_0 k \cos kx$, and solutions to eqn [1] subject to this lower boundary condition may be written in the form

$$w(x, z) = \tilde{w}_1(z) \cos kx + \tilde{w}_2(z) \sin kx. \quad [3]$$

Substituting eqn [3] into eqn [1], one obtains

$$\frac{d^2 \tilde{w}_i}{dz^2} + (\ell^2 - k^2) \tilde{w}_i = 0 \quad i = 1, 2. \quad [4]$$

Consider the simplest possible atmospheric structure in which N and U are constant with height. Without loss of generality we will focus on the case in which $U > 0$ and $k > 0$. Since N and U are constant, $\ell^2 = N^2/U^2$ is also constant. Defining $\nu = (\ell^2 - k^2)^{1/2}$ and $\mu^2 = -\nu^2$, the solution to eqn [4] may be written as

$$\tilde{w}_i(z) = \begin{cases} A_i e^{\mu z} + B_i e^{-\mu z} & k > \ell, \\ C_i \cos \nu z + D_i \sin \nu z & k < \ell, \end{cases} \quad [5]$$

where A , B , C , and D are constants to be determined by the upper and lower boundary conditions. Note that the fundamental character of the solution depends on the relative magnitudes of the Scorer parameter and the horizontal wavenumber.

If $\ell < k$, or equivalently, if the intrinsic frequency of the wave Uk is greater than N , solutions to eqn [4] either grow or decay exponentially with height. Only the solution that decays with height is admitted by the upper boundary condition that the perturbation energy density must approach zero as $z \rightarrow \infty$. The vertical velocity satisfying eqn [1] and the upper and lower boundary conditions is

$$w(x, z) = U h_0 k e^{-\mu z} \cos kx. \quad [6]$$

On the other hand, if $\ell > k$, the solutions to eqn [4] are sinusoidal functions of z that neither amplify nor decay as $z \rightarrow \infty$. After imposing the lower boundary condition, the general solution can be expressed as

$$w(x, z) = (U h_0 k - E) \cos(kx + \nu z) + E \cos(kx - \nu z), \quad [7]$$

where the constant E is determined by the upper boundary condition. Writing the solution in the form eqn [7] makes it easy to distinguish between waves that propagate energy upward or downward by examining the relationship between the signs of the vertical and horizontal wavenumbers.

The perturbation energy in a wave propagates at the group velocity. In the constant- N -and- U case, the dispersion relation for the time-dependent generalization of eqn [1] is

$$\omega = Uk \pm \frac{Nk}{(k^2 + \nu^2)^{1/2}}, \quad [8]$$

where ω is the frequency and k and ν are the horizontal and vertical wavenumbers in an arbitrary wave of the form $\Re(e^{i(kx + \nu z - \omega t)})$. Since by assumption $U > 0$, all steady waves (for which $\omega = 0$) are associated with the negative root in eqn [8], and their vertical group velocities are

$$\frac{\partial \omega}{\partial \nu} = \frac{Nk\nu}{(k^2 + \nu^2)^{3/2}}, \quad [9]$$

implying that upward group velocity, and upward energy transport, occurs when k and ν have the same sign. The upper boundary condition therefore requires $E = 0$ in eqn [7], and when $\ell > k$, the solution to eqn [1] becomes

$$w(x, z) = U h_0 k \cos(kx + \nu z). \quad [10]$$

The difference between the case $\ell < k$ and the case $\ell > k$ is illustrated in Figure 3, which shows streamlines over a series of sinusoidal ridges in a steady flow with $N = 0.01 \text{ s}^{-1}$ and $U = 15 \text{ m s}^{-1}$. In the case shown in Figure 3(a), the topographic wavelength is 8 km and $\ell^2 < k^2$ (or equivalently $Uk > N$); the waves decay exponentially with height, and the wave crests are aligned vertically. In the case in Figure 3(b), the topographic wavelength is 40 km and $\ell^2 > k^2$ (or $Uk < N$); the waves propagate vertically without loss of amplitude, and the wave crests tilt upstream with height. The waves decay away from the forcing when the intrinsic frequency exceeds the

Figure 3 Streamlines in steady airflow over an infinite series of sinusoidal ridges when $N = 0.01 \text{ s}^{-1}$, $U = 15 \text{ m s}^{-1}$, and the wavelength of the topography is (a) 8 km (case $Uk > N$) or (b) 40 km (case $Uk < N$). The flow is from left to right. The lowest streamline coincides with the topography.

Brunt-Väisälä frequency ($Uk > N$) because there is no way for buoyancy restoring forces to support oscillations at such high frequencies (see **Gravity Waves: Buoyancy and Buoyancy Waves: Optical Observations; Buoyancy and Buoyancy Waves: Theory**). On the other hand, when the intrinsic frequency is less than the Brunt-Väisälä frequency, vertical propagation occurs because buoyancy restoring forces can support air-parcel oscillations along a path slanted off the vertical at an angle $\phi = \cos^{-1}(Uk/N)$. In steady mountain waves, ϕ is the angle at which lines of constant phase tilt off the vertical.

Isolated Mountain, Vertical Variations in N or U

The mountain-wave solutions [6] and [10] are only valid for air streams with constant basic-state wind speed and stability flowing across an endless series of sinusoidal ridges. If more realistic terrain profiles and atmospheric structures are considered, other linear solutions can be obtained that more strongly resemble observed mountain waves. In this section, we will describe how the wave response is influenced by isolated topography and vertical variations in atmospheric wind speed and stability.

Suppose that the mountain profile consists of a single ridge from which the terrain elevation drops to some reference level at all distances sufficiently far upstream and downstream. Just as Fourier series can be used to represent a wide variety of periodic functions with an infinite sum of sines and cosines, the isolated mountain can, under rather general conditions, be constructed from periodic functions by the use of Fourier transforms. Let $\hat{w}(k, z)$ denote the Fourier transform of $w(x, z)$ with respect to the x -coordinate, and let $\hat{h}(k)$ be the Fourier transform of the topography $h(x)$.

The k -th component of the Fourier transformed vertical velocity $\hat{w}(k, z)$ must satisfy the Fourier transform of the governing eqn [1],

$$\frac{\partial^2 \hat{w}}{\partial z^2} + (\ell^2 - k^2) \hat{w} = 0, \quad [11]$$

which has the same form as eqn [4]. The lower boundary condition transforms to $\hat{w}(k, 0) = iUk\hat{h}_0\hat{h}$. When N and U are

constant, the solution to eqn [11], subject to the appropriate upper and lower boundary conditions, is

$$\hat{w}(k, z) = ikU\hat{h}(k) \exp\left[i(\ell^2 - k^2)^{1/2}z\right], \quad k > 0. \quad [12]$$

Equation [12] is just the complex analog of eqn [5]; each Fourier component $\hat{w}(k, z)$ of the transformed vertical velocity is identical to the $\hat{w}_i$ forced by an infinite series of sinusoidal ridges having wavenumber k and amplitude $\hat{h}(k)$. The solutions obtained in the preceding section are therefore also applicable to the case of isolated topography. The only complication arises from the requirement that after the $\hat{w}(k, z)$ are determined, the total vertical velocity $w(x, z)$ must be obtained by computing an inverse Fourier transform. The relative weight attached to each individual wavenumber in the composite solution is determined by the Fourier transform of the mountain.

Streamlines for steady linear flow over an isolated ridge of the form

$$h(x) = \frac{h_0 a^2}{x^2 + a^2} \quad [13]$$

are shown in Figure 4(a) for the case $N = 0.01047 \text{ s}^{-1}$, $U = 10 \text{ m s}^{-1}$, and $Nh_0/U = 0.6$.

In this case, $Na/U \approx 10$ and the dominant horizontal wavenumbers in the Fourier transform of the topography satisfy $k^2 \ll \ell^2$, which eliminates the dependence of the vertical structure on the horizontal wavenumber in eqn [12]. As a result, all modes associated with these dominant wavenumbers have approximately the same vertical wavelength ($2\pi U/N = 6 \text{ km}$), so the streamline at 6 km approximately reproduces the mountain profile while those at 3 and 9 km are roughly the mirror-image of the topography. The solution shown in Figure 4(a) is computed numerically without making the hydrostatic assumption and is very similar to that which would be obtained in the hydrostatic limit, in which all horizontal wavenumbers have exactly the same vertical wavelength and the mountain profile is exactly reproduced by the streamline originating at the 6 km level upstream.

As suggested by Figure 4(a), when an infinitely long ridge is sufficiently wide that the flow is approximately hydrostatic

Figure 4 Streamlines in steady airflow over an isolated mountain as predicted by linear theory when (a) $a = 10$ km, N is constant, and $Nh_0/U = 0.6$; (b) $a = 5$ km, N is constant throughout each of two layers such that between the surface and 3 km $N_l h_0/U = 0.6$, and above 3 km $N_u h_0/U = 0.24$.

($Na/U \gg 1$) but still narrow enough that Coriolis forces can be neglected ($|f|a/U \ll 1$, where f is the Coriolis parameter), energetic mountain waves are found only in the region directly above the mountain. In the nonhydrostatic case, some waves do appear in the region downstream from the ridge, as can be deduced from the horizontal group velocity $\partial\omega/\partial k$, which using eqn [8] and again assuming $U > 0$, may be expressed as

$$\frac{\partial\omega}{\partial k} = \frac{\omega}{k} + \frac{Nk^2}{(k^2 + \nu^2)^{3/2}}. \quad [14]$$

The first term in eqn [14] is the phase speed, which is zero for a steady mountain wave. The second term is nonnegative, implying downstream energy propagation – except in the hydrostatic limit when the second term vanishes because $k^2/\nu^2 \rightarrow 0$. A sufficient decrease in the width of the mountain, relative to that shown in Figure 4(a), will therefore lead to the generation of nonhydrostatic waves that populate a wedge-shaped region emanating upward and downstream from the mountain. The wave energy for each component of the total solution propagates along a line whose slope is equal to the ratio of the vertical group velocity to the horizontal group velocity for that component. Quasi-uniform low-level wave trains, such as those shown in Figure 4(b), do not however, occur unless there are significant vertical variations in the wind speed and static stability.

If the vertical variations in U and N are such that the Scorer parameter decreases significantly with height, cross-ridge flow may generate a qualitatively different type of wave, the ‘trapped lee wave.’ A series of trapped lee waves (also known as resonant lee waves) are apparent extending downstream from the ridge throughout the layer $0 \leq z \leq 4$ km in Figure 4(b); a vertically propagating wave is also visible directly above the mountain. The streamlines shown in Figure 4(b) are for the linear solution to the same problem considered in Figure 4(a), except that $a = 5$ km and the static stability above 3 km is reduced by a factor of 0.4. (The Brunt-Väisälä frequencies in the upper and lower layers are thus $N_u = 0.004188$ and $N_l = 0.01047$ s⁻¹, respectively.)

A necessary condition for the existence of trapped waves in the two-layer problem is that

$$\ell_L^2 - \ell_U^2 > \frac{\pi^2}{4H^2}, \quad [15]$$

where ℓ_U and ℓ_L are the Scorer parameters in the upper and lower layers, and H is the depth of the lower layer. Equation [15] states that the difference in wave propagation characteristics in the two layers must exceed a certain threshold before the waves can be trapped. The horizontal wavenumber of any resonant lee wave in the two-layer system satisfies $\ell_L > k > \ell_U$, implying that the wave propagates vertically in the lower layer and decays exponentially with height in the upper layer. As shown in Figure 4(b), trapped waves have no tilt, even though they can propagate vertically in the lower layer. The reason for this is that wave energy is repeatedly reflected, without loss of amplitude, from the upper layer and the flat ground downstream from the mountain. As a result, the downstream disturbance is the superposition of equal-amplitude upward and downward propagating waves, a combination which has no tilt.

Nonlinear Mountain Waves

Now suppose that the mountain height is not small compared to the vertical wavelength of the mountain wave. If N and U are constant, the streamline displacement $\delta(x, z)$ in steady two-dimensional Boussinesq flow over such a ridge is still governed by a relatively simple mathematical model known as Long’s equation

$$\frac{\partial^2 \delta}{\partial x^2} + \frac{\partial^2 \delta}{\partial z^2} + \frac{N^2}{U^2} \delta = 0, \quad [16]$$

Although Long’s equation is a linear partial differential equation, it may be derived from the fully nonlinear equations without making any linearization or small-amplitude assumptions. Nevertheless, eqn [16] may also be derived by assuming the mountain is infinitesimally high and linearizing the

Figure 5 As in [Figure 2](#) except that the streamlines are for a fully nonlinear flow as computed using a numerical model. The trapped waves in panel b are not completely steady; the solution is shown a nondimensional time $Ut/a = 20$ after starting the flow from rest.

governing equations in the usual manner. When N and U are constant, the only difference between the linear and nonlinear solutions arises from the lower boundary condition, which requires $\delta[x, h(x)] = h(x)$ in the exact finite-amplitude case and is approximated by $\delta(x, 0) = h(x)$ in the small-amplitude limit.

As one might guess from the similarities in the governing equations, when N and U are constant the influence of nonlinear dynamics on the wave structure is often relatively minor. This similarity can be appreciated by comparing the linear solution in [Figure 4\(a\)](#) with the corresponding nonlinear solution in [Figure 5\(a\)](#), both of which show streamlines in a Boussinesq flow for which $Nh_0/U = 0.6$.

Nonlinear processes steepen the streamlines around $z = 4.5$ km, which is $3/4$ of a vertical wavelength ($3\lambda_z/4$) above the topography. Conversely, the nonlinear waves are less steep than their linear counterparts near $z = 1.5$ km, which is $\lambda_z/4$ above the mean height of the topography. Despite these modest differences in the shape of the streamlines in the linear and nonlinear waves, the wave amplitude is almost identical in both cases. Nonlinear processes do not have a dramatic impact on the waves forced by flow over an infinitely long ridge unless either (i) there are vertical variations in N and U or (ii) the mountain is high enough to force wave overturning.

The influence of nonlinear wave dynamics on the flow in the two-layer atmosphere previously considered in connection with [Figure 4\(b\)](#) is shown in [Figure 5\(b\)](#). The amplitude of the lee waves in the nonlinear solution is much larger than that in the linear solution, and in the nonlinear case significant variations are visible among the individual troughs and crests in the region $65 \leq x \leq 100$ km. As suggested by this example, and demonstrated in several observational campaigns and numerical studies, linear theory does reliably predict the amplitude of trapped lee waves generated by finite-amplitude mountains. The main shortcoming of linear theory is that it cannot capture the tendency of the nonlinear dynamics to enhance the short-wavelength Fourier components in the low-level wave field over the lee slope. The nonlinear enhancement of these short-wavelength perturbations in the first wave above the mountain often produces more forcing at the wavelength of the resonant lee waves than does the direct forcing by the topographic profile itself.

Clouds that form in regions of net upward displacement in vertically propagating hydrostatic waves may appear like the cloud in [Figure 1](#). The large single region of cloudiness parallel to the mountain crest is probably formed by air-parcel displacements qualitatively similar to those in the streamline originating near the 6-km-level in [Figure 5\(a\)](#).

Clouds that form in trapped lee waves may appear as a series of long bands parallel to the generating ridge. Such bands are often visible in satellite photos and are formed by streamline patterns qualitatively similar to those originating in the layer between 2 and 4 km in [Figure 5\(b\)](#). Nevertheless, three dimensional variations in the upstream topography often break these bands into the superposition of many lens-shaped cloud masses, such those shown in [Figure 2](#).

Returning to the discussion of how nonlinear dynamics modify the structure of mountain waves, consider the influence of wave breaking on the flow. Two examples in which the wave amplitude becomes large enough to overturn are shown in [Figure 6](#).

The case shown in [Figure 6\(a\)](#) is one with constant N and U identical to that in [Figure 5\(a\)](#), except that the mountain height is increased so that $Nh_0/U = 1.2$. (The vertical scale also extends to $z = 15$ km.) Wave overturning first begins at the $3\lambda_z/4$ level, which is the same level at which the wave faces appear to be steepened in [Figure 5\(a\)](#). As the wave begins to overturn, a $\lambda_z/2$ deep region of well-mixed stagnant fluid develops over the lee slope and begins to extend downstream. A second region of wave overturning eventually develops at a height of $7\lambda_z/4$, although the perturbations are weaker at this level due to the dissipation experienced by the wave as it propagates through the first wave-breaking level. [Figure 6](#) shows the solution at a nondimensional time (Ut/a) of 30, by which time the near-mountain solution is quasi-steady, but the layers of well-mixed fluid in the wave-breaking region continue to expand further downstream. Also shown are contours of the subgrid-scale eddy diffusivity. Regions in which the subgrid-scale diffusivity is large are regions in which the numerical model has diagnosed the presence of vigorous small-scale turbulence such as that which occurs due to wave breaking.

Although the breaking of mountain waves in an atmosphere with constant N and U has received a great deal of theoretical attention, the morphology of such flows is not representative of

Figure 6 Streamlines (black), contours of the subgrid-scale eddy diffusivity (blue dot-dashed, at intervals of $20 \text{ m}^2 \text{ s}^{-1}$) and the vertical profile of the large-scale wind (red) for (a) the case shown in Figure 3(a) except that $Nh_0/U = 1.2$ and the vertical scale extends to 15 km; (b) as in (a) except with westerly wind shear throughout the tropopause and a realistic stratosphere (see text).

most real-world wave-breaking events, in which the wave structure is significantly modified by vertical wind shear in the upstream flow. Those ridges that run north–south in the middle latitudes are oriented perpendicular to the climatological westerly flow and are frequent generators of large-amplitude mountain waves. A prototypical example of the mountain waves generated by such ridges in a deep westerly flow is shown in Figure 6(b). The mountain profile, the surface wind speed (10 m s^{-1}), and the low-level stability (0.01047 s^{-1}) are identical to those for the case in Figure 6(a), but the upstream wind speed U increases linearly to 25 m s^{-1} at a height of 9 km. The presence of a stratosphere is modeled by increasing N to 0.02 s^{-1} above 9 km and linearly decreasing U back to 10 m s^{-1} at $z = 13 \text{ km}$. The wind speed is a constant 10 m s^{-1} above 13 km. The increase in the cross-mountain wind with height throughout the troposphere decreases the local value of the nonlinearity parameter $\varepsilon(z) = N(z)h_0/U(z)$ to a minimum just below the tropopause at $z = 9 \text{ km}$. Above the tropopause ε increases rapidly with height due to the factor-of-two increase in N and the reversal of the wind shear. As evident in Figure 6(b), these more realistic vertical variations in the upstream flow are sufficient to shift the primary region of wave breaking to the lower stratosphere (around $z = 12 \text{ km}$) and to prevent wave breaking in the troposphere.

The influence of wave breaking is highly nonlocal. In the case with constant N and U , the entire lee-side flow in the wave-breaking regime (Figure 6(a)) is dramatically different from that in the nonbreaking regime (Figure 5(a)). In particular, the surface winds above the lee slope are significantly enhanced in the wave-breaking regime (see Mountain Meteorology: Downslope Winds). The breaking waves in Figure 6(b) also exert a nontrivial influence on the low-level flow, although this influence is considerably less dramatic than that which develops as a consequence of wave breaking in Figure 6(a).

Vertical Momentum Transport

When air flowing over a mountain generates vertically propagating waves, a region of high pressure develops upstream of

the ridge crest and a region of low pressure appears in the lee. The distribution of these pressure perturbations is revealed by the along-flow variation in the spacing between the two lowest streamlines in Figures 3(b), 4(a), 5 and 6. The asymmetry in the pressure distribution across the ridge gives rise to a net pressure force on the topography that tends to accelerate the topography in the direction of the mean flow. An equal and opposite force is exerted on the mean flow by the topography.

To see how the topographically induced decelerative forcing is distributed throughout the fluid, consider the horizontal momentum eqn [17] in which $\mathbf{v}$ is the total velocity vector, p is the pressure, ρ is the density, $\mathbf{i}$ is the unit-vector along the x -coordinate, and $u = \mathbf{v} \cdot \mathbf{i}$,

$$\frac{\partial \rho u}{\partial t} + \nabla \cdot (\rho u \mathbf{v} + p \mathbf{i}) = 0. \quad [17]$$

Integrate the preceding throughout the volume between the surface $h(x)$ and an arbitrary level z_t ; use the divergence theorem; note that there is no advective momentum flux through the lower boundary, and assume that the domain is periodic in the horizontal, then

$$\frac{\partial}{\partial t} \iiint \rho u \, dV = - \iint \rho u w \, dx dy \Big|_{z=z_t} - \iint p \frac{\partial h}{\partial x} \, dx dy \Big|_{z=h}. \quad [18]$$

When vertically propagating mountain waves are present, the cross-mountain pressure drag (given by the last term in eqn [18]) must decelerate the volume-averaged flow in the layer between the surface and z_t unless that drag is balanced by a downward transfer of momentum through level z_t . This same result can be obtained for flow in nonperiodic domains under the assumption that the perturbation quantities vanish at the lateral boundaries, although caution is advised when trying to apply eqn [18] in a nonperiodic domain because non-negligible mountain-wave-induced perturbations may extend far upstream and downstream from a very long ridge.

The interaction between the mean flow and the mountain-wave induced momentum fluxes can be described more

precisely by separating the dynamical variables into an average over the domain (denoted by an overbar and taken as the representative of the synoptic-scale flow impinging on the mountain) and the perturbation about that average (denoted by a prime and assumed to represent the contributions from mountain waves generated by the flow over the ridge). If the horizontal momentum equation for two-dimensional inviscid Boussinesq flow,

$$\frac{\partial \rho_0 u}{\partial t} + \frac{\partial}{\partial x}(\rho_0 u^2 + p) + \frac{\partial}{\partial z}(\rho_0 u w) = 0, \quad [19]$$

is averaged over a periodic domain (or if it is assumed that the perturbations vanish at the lateral boundaries of a nonperiodic domain) and if $\bar{w} = 0$, one obtains

$$\frac{\partial \rho_0 \bar{u}}{\partial t} = -\frac{\partial}{\partial z}(\rho_0 \overline{u'w'}). \quad [20]$$

A decelerative forcing will therefore be exerted on the flow in those regions in which the mountain-wave-induced momentum flux is divergent, that is, where $\partial(\rho_0 \overline{u'w'})/\partial z > 0$.

The vertical profile of the momentum flux is particularly easy to describe for steady, inviscid, small-amplitude waves in a periodic domain (or in an unbounded domain in which the waves decay as $x \rightarrow \pm\infty$). The cross-mountain pressure drag in such waves is identical to the vertical momentum flux at $z = 0$, as may be seen from the steady-state version of eqn [18] in the limit $z_t \rightarrow 0$. Furthermore, a classic theorem due to Eliassen and Palm states that under the preceding assumptions $\rho_0 \overline{u'w'}$ is constant with height except at a 'critical level' at which $\bar{u} = 0$. Mountain waves are dissipated at the mean-state critical layers found in real atmospheric flows. Mountain waves are also dissipated through breaking and overturning if they attain sufficiently large amplitude due to the decrease in density with height or, as in Figure 6, if they propagate into a region in which the local value of N/U increases significantly. Small-amplitude mountain waves that propagate all the way to the mesosphere without experiencing overturning are damped by radiative heat transfer.

The Eliassen and Palm theorem implies that small-amplitude mountain waves transport a fraction of the momentum of the cross-mountain flow downward to the surface from those elevations at which the waves undergo dissipation. There will be no vertical momentum flux divergence and no forcing of the mean flow within the those layers of the atmosphere in which the waves are steady and nondissipative. The momentum fluxed downward by the waves is transferred to the topography by the cross-mountain pressure drag. Similar distributions of the vertical momentum flux are obtained even when the waves are nonlinear. For example, the vertical momentum flux profile associated with the finite-amplitude waves shown in Figure 6(b) is approximately nondivergent between the ground and the region of wave breaking in the layer $11 \leq z \leq 13$ km. In contrast, the momentum flux profile is strongly divergent in the wave breaking region, and the mean flow is subject to a significant decelerative forcing throughout this layer (see **Dynamical Meteorology: Wave Mean-Flow Interaction**). Unlike surface friction, the drag associated with mountain waves is typically exerted on the flow well above the lower boundary. Numerical experiments with general circulation models suggest that mountain-wave-induced drag plays a nontrivial role in the total momentum budget of the atmosphere.

Nonsteady Waves

The assumption that mountain waves are in steady state greatly simplifies their theoretical analysis and leads to predictions that are often in decent agreement with observations. Nevertheless, clear evidence of nonstationary behavior has also been documented, particularly in the case of trapped lee waves. Trapped waves are resonant oscillations whose amplitude and wavelength are quite sensitive to changes in the structure of the flow impinging on the mountain. Thus, rather modest changes in the large-scale wind speed and temperature profiles can produce easily observed variations in the lee wave train. Even when the large-scale synoptic forcing is essentially constant, lee-wave transience can be produced by either nonlinear wave-wave interactions or by the diurnal heating or cooling of the planetary boundary layer. Solar heating, for example, reduces the buoyancy frequency $N(z)$ in the lower atmosphere in a manner that typically tends to increase the wavelengths of trapped waves.

Although it can be more difficult to observe, changes in the large-scale flow also influence vertically propagating waves. One property of vertically propagating waves that is particularly sensitive to variations in the cross-mountain flow is the vertical profile of momentum flux. An example of this sensitivity is shown in Figure 7, which is a plot of $\rho_0 \overline{u'w'}$ as a function of time and height from a numerical simulation in which a localized jet crosses over an isolated ridge.

The large-scale winds are constant with height, and over the ridge crest they increase sinusoidally from zero to 20 m s^{-1} and then fall back to zero over a 50-h period. Throughout the domain $N = 0.01 \text{ s}^{-1}$, so at specific times during the simulation, the flow in a vertical plane perpendicular to the ridge-line

Figure 7 Horizontal-domain-averaged momentum flux $\rho_0 \overline{u'w'}$ generated by time-varying flow over a 750-m high ridge plotted as a function of time and height. Values are normalized by the momentum flux for the linear steady-state solution for waves driven by a 20 m s^{-1} flow across the same ridge. Solid lines show contours at intervals of 0.25, with values in the range (0.5,1.0), (1.0,1.75), and greater than 1.75 shaded gray, orange, and dark orange-red, respectively. Adapted with permission from Chen, C.C., Durran, D.R., Hakim, G.J., 2005. Mountain wave momentum flux in an evolving synoptic-scale flow. *Journal of Atmospheric Sciences* 62, 3213–3231.

is roughly similar to that shown in Figures 5(a) and 6(a), except that the ridge in the simulation used to produce Figure 7 is 750 m high. The actual momentum flux is normalized by the flux produced by linear waves over a mountain of the same height and shape in a steady uniform 20 m s^{-1} flow (with the same value of $N = 0.01 \text{ s}^{-1}$). As a point of reference, if nonlinear processes were negligible, and if the 50-h period over which the flow varies were sufficiently long that the waves could be considered steady, the Eliassen-Palm theorem would apply, in which case every contour drawn in Figure 7 would be a straight vertical line and the contours would be symmetric about hour 25 because the momentum flux would be linearly proportional to the wind speed. Because of the normalization, the contour at hour 25 would have a value of unity, and there would be no orange region on the plot.

Yet as apparent in Figure 7, the momentum fluxes are not symmetric about hour 25, but are much stronger when the large-scale flow is accelerating ($t < 25 \text{ h}$) than when it is decelerating ($t > 25 \text{ h}$). For example, the momentum flux is three times stronger at hour 19 than at hour 31, even though the large-scale wind above the ridge at both times is identical. Moreover, the flux aloft at hour 19 is more than twice as strong as the flux that would be predicted to occur at the time of strongest flow using a steady-state analysis. This momentum-flux enhancement may be explained by noting that each packet of wave energy launched while the mountain wave is present moves upward at the group velocity. In this example, the vertical group velocity of each packet is proportional to the large-scale cross-mountain wind speed at the time the packet was launched. As a consequence, packets launched later in the acceleration phase tend to overtake those launched earlier and accumulate above the mountain, creating higher momentum fluxes while the cross-mountain flow is accelerating.

The drag generated by the vertical divergence of mountain-wave generated momentum fluxes is currently parameterized in global atmospheric models for both weather forecasting and climate simulation. The formulation of accurate 'gravity-wave-drag' parameterizations is greatly complicated both by the nonlinearity of finite-amplitude mountain waves in (compare Figures 4(b) and 5(b)) and by the dependence of the flux on the past history of the large-scale flow.

Introduction

Since the beginning of systematic studies on cyclone tracks, it has been noted that many mountain ranges act as preferred locations for cyclogenesis. An illustration of this is provided in Figure 1 in terms of cyclogenetic areas and associated storm tracks. The chart is based on hand-counted frequencies of closed isobars on sea-level pressure charts. Besides the classical Atlantic and Pacific storm tracks that emanate to the east of the continents, a range of smaller-scale cyclogenetic areas can be identified in close vicinity to topographic obstacles. Particularly worth noting is the elongated region to the lee of the Rocky Mountains, the Gulf of Genoa to the south of the Alps, and an area near the southern tip of Greenland. In the literature, many additional regions of orographic cyclogenesis are documented. In the Northern Hemisphere this includes the Atlas mountain range in Algeria, the central Japanese mountains, the Tibetan plateau, and the Altai mountains. In the Southern Hemisphere, orographic cyclogenesis is less abundant but has, for instance, been reported for the Andes and the Transantarctic mountain range.

The mountains under consideration are thus characterized by a wide range of horizontal scales, and include both 'synoptic-scale mountains' such as Greenland and the Rocky mountains, as well as 'meso-scale ranges' such as the European Alps, the Pyrenees, and the Atlas, to mention just a few. Here we will focus attention upon orographic cyclogenesis to the lee of the Rocky mountains and the Alps, and thereby cover examples from both these categories.

Synoptic and Climatological Description

Alpine Lee Cyclogenesis

The Alps are an arc-shaped mountain range ~800 km long that has a mean halfwidth of $L \approx 100$ km and an average ridge height of $H \approx 3$ km. Additional distinctive features of the range are major valleys that run predominantly north or south onto the foreland and connect at several Alpine passes, typically with altitudes between 1800 and 2500 m. The highest peaks of the Alps reach up to 4800 m.

Alpine lee cyclogenesis has been the subject of intense observational, theoretical, and numerical studies during the last decades. Numerous case studies, partly based on the Alpine Experiment (ALPEX) conducted in 1982, provide a comparatively coherent picture of the main features of an Alpine event. The pertinent synoptic setting of an Alpine lee cyclogenesis event is the approach of a cyclone toward central or northern Europe and the passage of the associated cold front with an accompanying upper-level trough toward the Alpine ridge (see Figure 2). The approach of this system initiates a highly transient phase of Alpine weather, with a duration of normally 2–3 days. Ahead of the approaching cold front, there is usually

southwesterly flow toward the Alps. The respective airstream consists of warm and moist air, is comparatively weakly stratified, and is associated with high wind velocities. It is able to rise over the Alpine ridge, leading to South Föhn to the north (Figure 2(a)). The cold air behind the cold front, however, is more stably stratified and often capped by a pronounced inversion. It is usually unable to climb the Alps but is rather deflected laterally. The orographic interception of the front is accompanied on the windward side by retardation, low-level blocking, and flow splitting; by the steepening of the baroclinic zone; by the build-up of an impressive pressure gradient across the Alpine barrier; and by the generation of the Mistral flow to the west (Figure 2(b)) and Bora to the east of the Alps (Figure 2(c)).

To the lee the cyclogenesis evolves in two phases: a first phase comprising the *in situ* rapid development of a surface mesoscale low, followed by a less rapid phase involving an increase in both the horizontal and vertical scales of the system together with its possible translation away from the immediate lee region. The second phase is characterized by the arrival in the lee of an upper-level trough. In the absence of a suitable phase relationship between the low-level incipient cyclone and the upper-level trough, the shallow firstphase vortex is unable to grow vertically and decays quickly. Deep cyclones, on the other hand, detach from the Alps and take on the characteristics of typical extratropical depressions.

On average, about 30 Alpine lee cyclones are observed per year, with maximum frequency during the spring and autumn seasons. The climatological distribution of lee cyclogenesis suggests a predominant formation near the south-western tip of the Alps over the Gulf of Genoa. This geographic concentration betokens an orographic influence. Once a deep lee cyclone has formed, it becomes an important governor of the regional weather and climate. Lee cyclones often attain maximum strength when located over northern Italy, and the associated strong southerly flow ahead of the cyclone can induce storm surges in the Adriatic Sea (which occasionally threaten Venice) and advect moist Mediterranean air toward the Alps (which substantially contributes to the annual precipitation totals in northern Italy and the eastern Alps). Following their formation, lee cyclones propagate toward the east, following one of two major tracks. The first leads across the eastern Alps into eastern Europe, while the second follows the northern border of the Mediterranean Sea. As a result, Alpine lee cyclones are crucial to the precipitation climate in the eastern Mediterranean region.

Rocky Mountain Lee Cyclogenesis

The Rocky Mountains are oriented approximately north–south from Alaska to central Mexico, and are characterized by a mean ridge height of ~3 km. Their length and width correspond to

Figure 1 Cyclogenetic areas and associated storm tracks in the Northern Hemisphere for January, based on hand-counted frequency of closed isobars on conventional surface pressure charts (with 4 hPa contour interval). The two panels relate to (a) cyclogenetic regions (new closed low maintained for at least 24 h), and (b) the frequency of cyclones. The numbers relate to the counts on a $5^\circ \times 5^\circ$ grid during the 20 Januaries from 1958 to 1977. Reproduced from Whittaker, L.M., Horn, L.H., 1984. Northern hemisphere extratropical cyclone activity for four mid-season months. *International Journal of Climatology* 4, 297–310.

approximately 4000 km and 800 km in the north–south and west–east directions, respectively, and these scales exceed those of the Alps by almost an order of magnitude.

Rocky Mountain lee cyclogenesis usually starts with an anticyclone residing over the mountain, and an incident low-pressure system over the Pacific (see [Figure 3\(a\)](#)). As the Pacific low approaches the continent, it moves poleward ([Figure 3\(b\)](#)) and finally disappears ([Figure 3\(c\)](#)), while the initial high-pressure system moves south-eastward. Slightly prior to the arrival of the upper-level trough, a new surface low forms, typically 1000 km to the south of the last windward position of the Pacific low. After the upper-level trough has propagated over the Rocky Mountains, a deep development may follow. Usually the lee cyclone moves somewhat farther south before it propagates eastward and finally joins the Atlantic storm track. Strictly speaking, these events do not necessarily invoke a ‘new’ cyclone, but may be interpreted as an anomalous southward propagation of the low when crossing the Rockies (whereby the cyclone is masked by the mountain anticyclone), followed by regeneration in phase with the arrival of the upper-level trough.

Case studies have identified a series of associated mesoscale processes. When the parent cold front impinges upon the Rockies, observations demonstrate that there is frontal retardation, associated frontogenesis, and often the formation of an impressive tropopause fold that implies a descent of stratospheric air toward the cyclonic region. The relevance of Rocky Mountain cyclogenesis for the mid-west is evident from the frequent explosive developments, which often have important repercussions in terms of extreme weather events. Distinct frequency maxima are found, both in winter and summer, to the east of the highest parts of the Rockies in Alberta and Colorado.

Dynamical Mechanisms

There is a great variety of orographic depressions, ranging from small mesoscale vortices that may involve latent heating and convection, to deep lee cyclones that during their life cycle approach the typical structure of extratropical cyclones. Here attention is restricted to the latter category. The development of these deep lee cyclones involves – at least in the second phase – the typical ingredients of regular extratropical cyclogenesis, such as a vertical coupling between low-level thermal and upper-level potential vorticity (PV) anomalies (see **Synoptic Meteorology: Cyclogenesis**), sometimes affected by concomitant intensification by diabatic effects. Often lee cyclones form in an environment that would seem to support cyclogenesis even in the absence of topography. Numerical experiments with and without orography suggest that the role of the topography is often to trigger and modulate cyclogenesis, which would otherwise occur in the near vicinity and/or somewhat later in time. Despite the close relationship to regular mid-latitude cyclogenesis, a great variety of orographic mechanisms have been proposed, which may act in concert with classical cyclogenetic processes. Some of the key dynamical mechanisms are reviewed below.

Regime Diagram for Steady Flow Past Topography

While lee cyclogenesis is always a highly transient feature, essential aspects of its dynamics can be understood by resorting to the theory of steady flows past isolated topography. Here consideration is given to the dry flow of an airstream of uniform upstream velocity U and Brunt–Väisälä-frequency N toward a circular obstacle of height H , horizontal scale L , and shape $H(1 + r^2/L^2)^{-3/2}$. Assuming free-slip lower boundary

Figure 2 Schematics of an Alpine lee cyclogenesis event showing (a) incipient cold front, (b) cyclone formation, and (c) detachment of cyclone from the Alps. The bold arrows depict low-level air streams with light and dark shading indicating air streams ahead and behind the cold-front. The thin arrows show the upper-level flow.

conditions and hydrostatic dynamics, the flow-response is governed by two dimensionless parameters. These are a Rossby number based on the mountain width, (eqn [1], with f denoting the Coriolis parameter) and a dimensionless mountain height (eqn [2]), which is sometimes referred to as inverse Froude number.

$$R_o = \frac{u}{Lf} \quad [1]$$

$$\varepsilon = \frac{NH}{u} \quad [2]$$

The regime diagram spanned by these parameters is considered in Figure 4.

For the flow system described above, quasi-geostrophic solutions for an unbounded atmosphere exist provided that the dimensionless slope of the obstacle satisfies eqn [3].

$$R_o \varepsilon = \frac{NH}{Lf} < \frac{1}{2} \quad [3]$$

The respective regime boundary is included in Figure 4 as a bold line. The consideration of higher-order balance beyond the quasi-geostrophic system does not notably extend the validity of the balanced dynamics. The main feature of the quasi-geostrophic flow response is the presence of an anticyclone sitting over the mountain top. This is generated by vortex tube compression as the flow is directed over the obstacle. In the Northern Hemisphere, the presence of the mountain anticyclone implies an accelerated (decelerated) flow on the left-hand (right-hand) flank of the mountain (looking downstream). Flows with $\varepsilon > \varepsilon_{\text{cap}} = 3\sqrt{3}/2$ are in addition characterized by a stagnation point and a concomitant Taylor cap (a vertically confined region of closed streamlines), but these flows appear not very relevant to atmospheric conditions.

In the absence of background rotation ($R_o = \infty$), the dimensionless mountain height is the single control parameter in the limit of the inviscid and adiabatic dynamics with a free-slip lower boundary condition. Thus the flow response does not depend upon the slope of the obstacle, but on its height alone. Idealized numerical simulations have served to identify the major flow regimes. For configurations with $\varepsilon < \varepsilon_{\text{crit}} \approx 1.2$, where $\varepsilon_{\text{crit}}$ denotes the critical mountain height, the flow is essentially inviscid and adiabatic, and predominantly directed over (rather than around) the obstacle. In contrast, for $\varepsilon > \varepsilon_{\text{crit}}$, there is low-level flow splitting and the flow is around the obstacle. The later configuration implies the breakdown of the inviscid dynamics due to gravity-wave breaking and/or flow separation, and leads to the formation of a wake. In the presence of background rotation ($R_o < \infty$), the critical mountain height increases with the Rossby number. The respective regime boundary is included in Figure 4 as a bold line. Unlike the regime boundary for balanced solutions, it represents a sharp transition that involves a bifurcation.

To conclude the discussion, the typical range of the flow parameters (R_o, ε) has been included in Figure 4 for several major mountains of the Earth. The parameter range gives a crude estimate that takes into account atmospheric variability. The horizontal scale of the mountains considered has been estimated from topographic maps. In the case of

Figure 3 Schematics of Rocky Mountain Lee Cyclogenesis at approximately 12 h intervals. The shading represents a simplified orography with terrain higher than 1500 m. The heavy solid lines denote surface fronts, the solid lines the 1000 hPa geopotential, the dashed lines the 500 hPa geopotential, and the dash-dotted line the position of the upper-level trough. From Palmén and Newton, 1969.

elongated obstacles, the assigned horizontal scale L is based upon the width (rather than the length) of the mountain. For the mountain height, the maximum height has been selected in the case of isolated mountain peaks (e.g., for the Matterhorn), and the mean ridge height in the case of complex mountain ranges (e.g., for the Rocky Mountains and the Alps).

Two important inferences follow from Figure 4. First, most mesoscale mountain ranges (such as the European or Southern Alps) do not allow for a confident application of the quasi-geostrophic or balanced dynamics. For typical mid-latitude values of $f/N \approx 0.01$, the breakdown of the quasi-geostrophic dynamics occurs for obstacle slopes of $H/L \approx 0.005$. Mesoscale mountain ranges thus have horizontal scales that are about half an order of magnitude too small for confident application of the quasi-geostrophic theory. In the case of

strong flow or weak stability, quasi-geostrophic theory may, however, be qualitatively applicable to the flow past the Rocky Mountains or Greenland. Second, most major mountain ranges of the Earth are characterized by a height that often or always exceeds the critical dimensionless mountain height for flow splitting. For many mountain ranges, both flow regimes are possible, depending upon the ambient atmospheric conditions. This implies that regime transition from flowover to flow-around or vice versa may occur.

The Quasi-Geostrophic Framework in the Presence of Topography

The simplest theory for cyclogenesis in the absence of topography is due to Eady's work and applies the framework of the

Figure 4 Regime diagram for idealized stratified flows past an isolated obstacle of height H , halfwidth L , and shape $H(1 + L^2/L^2)^{-3/2}$, for an upstream profile characterized by uniform values of U and N . Regime boundaries are indicated by bold lines (see text for details) and the typical parameter ranges of several major mountain ranges are also included.

quasi-geostrophic dynamics (see **Dynamical Meteorology: Quasigeostrophic Theory**) to a continuously stratified atmosphere of uniform PV, confined above and below by the surface and a rigid lid. Several attempts have been made to apply this framework to orographic cyclogenesis. Here we begin by considering the dynamical foundations of these studies and consider the quasi-geostrophic dynamics of an adiabatic and inviscid Boussinesq atmosphere on an f -plane. The dynamics is governed by the conservation of relative potential vorticity q^* (eqn [4]) in the interior of the fluid, the thermodynamic equation [5] on the horizontal bounding surfaces, and the hydrostatic relation [6]).

$$\frac{D_g q^*}{Dt} = 0 \quad \text{with} \quad q^* = \zeta_g + \frac{f^2}{N^2} \frac{\partial^2}{\partial z^2} \left(\frac{p^*}{\rho_0} \right) \quad [4]$$

$$\frac{D_g}{Dt} \left(\frac{g\theta^*}{\Theta} \right) + wN^2 = 0 \quad [5]$$

$$\frac{\partial}{\partial z} \left(\frac{p^*}{\rho_0} \right) = \frac{g\theta^*}{\Theta} \quad [6]$$

Here the starred quantities denote the deviation from the Boussinesq background state (ρ_0, θ_0, p_0) of constant Brunt–

Väisälä frequency N , Θ is a constant reference potential temperature, the D_g/Dt operator refers to the total derivative following the geostrophic motion (eqn [7]), and ζ_g is the relative geostrophic vorticity $\zeta_g = -\partial u_g/\partial y + \partial v_g/\partial x$.

$$(u_g, v_g) = \frac{1}{f} \left(-\frac{\partial}{\partial y}, \frac{\partial}{\partial x} \right) \frac{p^*}{\rho_0} \quad [7]$$

For the classical Eady problem, the atmosphere is confined above and below by rigid horizontal surfaces at $z = 0$ and z_T , representing the Earth's surface and a rigid tropopause. In the presence of topography, several studies have employed the 'shallow-mountain' approximation, whereby the lower boundary condition is applied at $z = 0$ rather than at the real topographic height. This yields eqn [8], with $h(x, y)$ denoting the height of the specified orography.

$$w = \begin{cases} \mathbf{v}_g \cdot \nabla h & \text{for } z = 0 \\ 0 & \text{for } z = z_T \end{cases} \quad [8]$$

In effect, the shallow-mountain approximation replaces the mountain by 'equivalent' inflow and outflow through the plane $z = 0$, while it retains other nonlinearities of the flow. In comparison with the full lower boundary condition, the shallow-mountain approximation can be shown to properly represent the mountain volume (and thus the far-field circulation), while it underestimates the mountain height and slope.

If the flow is of constant PV at an initial time $t = 0$, then eqn [4] implies that it remains so forever. In this case, the governing equations may further be simplified. Upon defining the quasi-geostrophic streamfunction [9], eqn [4] simplifies to a homogeneous elliptic equation [10].

$$\psi = \frac{1}{f} \frac{p^*}{\rho_0} \quad [9]$$

$$q^* = \nabla_h^2 \psi + \frac{f}{N^2} \frac{\partial^2 \psi}{\partial z^2} = 0 \quad [10]$$

The lower and upper boundary conditions are of Neumann type and determined by the thermodynamic equation [5] in combination with the simplified boundary conditions [8].

$$\frac{D_g}{Dt} \left(\frac{\partial \psi}{\partial z} \right) + \frac{N^2}{f} w = 0 \quad \text{for } z = 0, z_T \quad [11]$$

Some of the mechanisms to be discussed below are directly based on the quasi-geostrophic system as laid out above; for others it will be necessary to relax the quasi-geostrophic assumption for a part of the relevant processes.

Modification of Baroclinic Instability

One of the early theories of lee cyclogenesis views orographic cyclogenesis either as a modification of baroclinic instability by topography or as a scattering problem studying the effects of topography on incident growing baroclinic modes. These theories in essence represent a modification of Eady's problem. The basic state flow is thus assigned a vertically sheared baroclinic structure (eqn [12]).

$$U(z) = \Lambda z \quad [12]$$

In the absence of topography, the linearization in a periodic channel yields the classical Eady instability problem, which supports growing baroclinic modes.

In the presence of topography, the linearized version of the simplified lower boundary condition [8] is combined with [12] to give eqn [13], where dashed quantities denote the perturbation.

$$w' = \mathbf{v}'_g \cdot \nabla h \quad (z = 0) \quad [13]$$

It is important to note that the shallow-mountain approximation in combination with $U(z=0) = 0$ implies that only the perturbation can interact with the topography, but not the basic state flow itself. Anticyclonic and cyclonic vorticity may

then be generated through vortex tube compression and expansion, and this occurs when the perturbation flow is respectively up and down sloping topography. The first-order response is sketched in Figure 5 for two different geometries of an idealized elongated obstacle with a length scale of several thousand kilometers. When the topography is aligned from north to south (as for the Rocky Mountains), an incident low experiences strengthening to the north and weakening to the south over the upstream slope of the topography, and the opposite pattern downstream. When the topography is aligned from west to east (as qualitatively the case for the Alps, but note the difference in scale), the effect of the topography is to induce a low-high pressure dipole across the obstacle, the sign of which is determined by the phase of the wave.

The full mathematical problem of orographically modified normal modes may be dealt with either analytically using expansion techniques, or numerically using a continuously stratified or two-layer model. An example of a numerical solution is reproduced in Figure 6, which shows the surface streamfunction of a growing mode for the geometry of the Rocky Mountain. Upstream of the obstacle, the low drifts toward north and weakens, while a new surface low reappears to the lee in the south. This sequence of events is qualitatively comparable with that of observed Rocky Mountain lee cyclogenesis events (see Figure 3).

An important feature of the baroclinic instability mechanism of lee cyclogenesis is that the growth rates of the classical baroclinic problem are reduced by the presence of topography (since it inhibits meridional advection of low-level air). Thus, the mechanism is unable to explain the rapid growth rates that are commonly observed in the first phase of Alpine lee cyclogenesis events, for example.

Generation of Baroclinic Lee Waves

In comparison to the baroclinic instability mechanism discussed above, the baroclinic lee wave theory does not include any baroclinic growth but provides a possible explanation for the rapid initial growth and pressure drop. The theory is based on essentially the same dynamical framework as detailed above, with the following alterations. First, the rigid-lid atmosphere is replaced by an unbounded atmosphere $0 \leq z \leq \infty$. By avoiding the rigid lid (the Eady problem) and the β -plane (the Charney problem), baroclinic waves are stabilized in spite of the available potential energy. Second, the basic-state flow is replaced by eqn [14].

Figure 5 First-order vorticity generation (+) and destruction (−) by vortex stretching for the baroclinic instability mechanism of lee cyclogenesis. The two panels show the interaction of an Eady mode with west–east and north–south oriented topographic obstacles, respectively.

Figure 6 Example of an orographically modified normal mode for the geometry of the Rocky Mountain lee cyclogenesis. The panels (a) to (f) show the phases of the development in terms of the low-level streamfunction. Reproduced from Buzzi, A., Speranza, A., Tibaldi, S., Tosi, E., 1987. A unified theory of orographic influences upon cyclogenesis. *Meteorology and Atmospheric Physics* 36, 91–107.

$$U(z) = U_0 + \Lambda z \quad [14]$$

Unlike eqn [12], this flow may have $U(z) \neq 0$, and thus include the interaction of the basic-state flow with the underlying topography. The choice of this particular configuration allows for a clear distinction between unstable baroclinic growth (previous subsection) and orographic forcing (this subsection).

The baroclinic waves supported by this unbounded configuration are surface-trapped and decay exponentially with height. For a two-dimensional wave with wavenumber k and in absence of topography, the quasi-geostrophic streamfunction is given by eqn [15].

$$\psi'(x, z) \propto e^{-z/S} e^{i(kx + \omega t)} \quad [15]$$

In eqn [15], ω denotes the frequency, and eqn [16] gives the steering level.

$$S = \frac{f}{N} |k|^{-1} \quad [16]$$

The phase velocity of these waves is determined by the wind at the steering level (eqn [17]).

$$c_p = S(z = H) \quad [17]$$

The system supports stationary baroclinic waves provided there is a wind-reversal at some height S^* , i.e., $U(z = S^*) = 0$. The wavelength of these waves may then be obtained from eqn [16].

The baroclinic lee-wave theory views the initial rapid phase of lee cyclogenesis as the formation of a standing baroclinic

Figure 7 Transient development of a standing baroclinic wave to the lee of a two-dimensional ridge in a sheared background flow. The initial mountain anticyclone exhibits a rapid decay and there is a strong pressure drop to the lee (surface pressure (in hPa)). The dashed curve shows the asymptotic steady-state lee wave. The distance covered by the group velocity is indicated by the dot on each curve. Reproduced from Smith, R.B., 1984. A theory of lee cyclogenesis. *Journal of the Atmospheric Sciences* 41, 1159–1168.

lee wave in an initial-value problem. An example for a two-dimensional configuration (with the x -axes pointing perpendicular to an infinite ridge) is shown in [Figure 7](#). Starting from some initial conditions (here from the mountain anticyclone), a standing baroclinic wave quickly develops, with an associated rapid pressure drop of 35 hPa in 24 h. The key requirement of this mechanism is the presence of a wind-reversal with height, a configuration that is often (but not always) met in the Alpine cases but is rarely met with Rocky Mountain lee cyclogenesis.

Low-Level Blocking of Approaching Cold Air

The mechanisms discussed in the previous two subsections are entirely based on the quasi-geostrophic dynamics (assuming small Rossby numbers) and on a simplified lower boundary condition (implying absence of flow splitting). As discussed above, these conditions are rarely met with major topographic obstacles. Most orographic cyclones thus entail the violation of the balanced and the inviscid dynamics during the first phase of their development. Nevertheless, the formation of the mature cyclone during a second phase is likely to follow a largely balanced evolution. A dynamical interpretation may be sought by considering the first-phase unbalanced generation of orographic flow perturbations but assuming that their second-phase interaction with the synoptic-scale dynamics is approximately balanced. It then follows from the invertibility principle that relevant orographic perturbations must be associated with (i) a surface potential temperature anomaly (to be treated in this subsection), and/or (ii) an internal PV anomaly (to be

treated in the next subsection). These flow anomalies in essence represent a conceptual intermediary between the (unbalanced) mesoscale dynamics, and the subsequent (essentially balanced) interaction of orographically generated flow anomalies with the synoptic-scale environment.

A well-documented mechanism for the generation of surface potential temperature anomalies is the retardation and deformation of an approaching cold front. When cold air advection interacts with orographic flow splitting, a warm anomaly results within the sheltered lee of the obstacle. An example of this process is presented in [Figure 8](#). It shows an Alpine trajectory analysis derived from a real-case numerical simulation (with 14 km horizontal resolution). The starting points for the relevant trajectories were selected immediately behind an impinging cold front. Pronounced flow splitting occurs and the track of the trajectories encompasses an extended wake region that is ~ 5 K warmer than the surrounding air. It is important to realize that the scale of the resulting surface- θ anomaly may differ from that of the topography. In the example shown, the wake anomaly has an extension of almost 1000 km in the downstream direction, exceeding the Alpine width by a large factor. A surface anomaly of this size can well interact with the larger-scale balanced part of the flow evolution.

The orographic retardation of cold air advection implies geostrophic (or higher-order balanced) adjustment of the heavily distorted baroclinic configuration. This may induce a pressure drop and associated vertical motion. However, from the viewpoint of the balanced dynamics, it is the warm

Figure 8 Splitting of an incident low-level airstream (initially located at the 850 hPa level) by the Alps. The figure derives from three-dimensional 54 h trajectory computations driven by a numerical simulation of a cold-frontal passage on 30 April 1982. Reproduced from Kljun, N., Sprenger, M., Schär, C., 2001. The modification of a front by the Alps: a case study using the ALPEx reanalysis data set. *Meteorology and Atmospheric Physics* 78, 89–105.

low-level air itself that constitutes the driving agent of this development. The implications in terms of surface pressure perturbation may be estimated from quasi-geostrophic theory. To this end, consider a circular surface- θ anomaly of the form of eqn [18], with r denoting the radius and L its horizontal scale.

$$\theta^*(r, z = 0) = \Delta\theta \left[\left(\frac{r}{L} \right)^2 + 1 \right]^{-1/2} \quad [18]$$

In an unbounded atmosphere, the associated three-dimensional quasi-geostrophic streamfunction can be found by solving eqn [10] subject to the lower boundary condition obtained from the hydrostatic relation [6], i.e.,

$$\frac{\partial \psi}{\partial z} = \frac{1}{f} \frac{g\theta^*}{\Theta} \quad [19]$$

It can easily be verified that expression [20] is the desired solution.

$$\psi(r, z) = -\frac{g\Delta\theta}{\Theta} \frac{L}{N} \left[\left(\frac{r}{L} \right)^2 + \left(\frac{N}{f} \frac{z}{L} + 1 \right)^2 \right]^{-3/2} \quad [20]$$

Thus, the surface pressure perturbation in the center of the anomaly is given by eqn [21].

$$\Delta p = -f\rho_0 \frac{L}{N} \frac{g\Delta\theta}{\Theta} \quad [21]$$

Using typical mid-latitude values for f and N , and a potential temperature anomaly with an amplitude of $\Delta\theta = 10$ K and a horizontal scale of $L = 500$ km, one finds a pressure perturbation with an appreciable amplitude of ~ 17 hPa.

Generation of Low-Level Potential Vorticity Anomalies

In addition to surface potential temperature anomalies, orographic wakes comprise low-level internal PV anomalies that may interact with the balanced synoptic-scale environment. The generation of such PV anomalies is intimately related to the generation of lee vortices (see **Mountain Meteorology: Lee Vortices**). In essence, PV in lee vortices results from the violation of PV conservation by diabatic or viscous processes. Relevant processes for orographic flows include surface friction, dissipation by either gravity-wave breaking or flow separation, and diabatic heating associated with orographic precipitation. The formation of lee vortices is familiar from mountainous islands, where they may lead to spectacular Karman vortex streets on satellite pictures.

Wakes with low-level PV features can often be identified in numerical weather prediction models. In the case of the Alps, the formation of elongated PV streamers in the wake appears to occur almost whenever there is appreciable flow past the Alpine ridge. An example is shown in the left-hand panels of **Figure 9**. These show the formation of a large number of orographic PV streamers at the 850 hPa level, which will be referred to as ‘PV banners’. The situation considered is that of a cold frontal passage followed by deep lee cyclogenesis. The figure is based on a mesoscale simulation with a horizontal resolution of 14 km.

Individual pairs of banners with anomalously positive and negative values of PV can be attributed to individual flow-splitting events, either on the scale of the whole of the Alps (primary banners) or on that of individual massifs and peaks of

Figure 9 Potential vorticity (PV units) and horizontal wind vectors on the 850 hPa level for an Alpine lee cyclogenesis event. The data are from real-case numerical simulations using the full topography (left-hand panels) and a simplified topography (right-hand panels), respectively. The heavy lines denote topographic height at 1000 and 2200 m. Reproduced from Aebischer, U., Schär, C., 1998. Low-level potential vorticity and cyclogenesis to the lee of the Alps. *Journal of the Atmospheric Sciences* 55, 186–207.

the model topography (secondary banners). The simulated PV banners have amplitudes of several PV units, and grow in length when the orographically generated PV anomalies are advected downstream. In this way, Alpine banners can attain a length of up to 1500 km on occasions. The existence and apparent stability (with respect to shedding instabilities) of such banners has been verified observationally within the Mesoscale Alpine Programme (MAP) conducted in 1999.

The formation of a multitude of banners has implications for their far-field effects, and thus their ability to affect the balanced dynamics.

In essence, the far-field effect will be dominated by the primary (outermost) banners, while the effect of the secondary banners will decay quickly with height, as governed by the associated Rossby depth of deformation af/N , where a denotes the distance between neighboring banners. Only the primary banners may invoke deep interaction with other flow features, such as an approaching upper-level PV streamer. The right-hand panels of [Figure 9](#) suggest this kind of effect. The respective simulation is identical to that in the left-hand panels, except for the use of idealized ellipsoidal topography. It shows how the primary PV banner to the west of the Alpine ridge rolls up and contributes to the low-level PV within the initial core of the developing lee cyclone.

Synthesis

In the 1980s, the multitude of processes that can contribute to lee cyclogenesis triggered a scientific debate about lee cyclogenesis theories. A sophisticated testing methodology was developed that involves projecting the key assumptions of a theory (such as a linearization strategy and lower boundary conditions) onto a numerical simulation of a lee cyclogenesis event. The methodology is applicable to theories with well-defined mathematical stipulations (such as the modified baroclinic instability and the baroclinic lee-wave mechanisms discussed above). The application of the testing methodology has demonstrated that none of the tested mechanisms alone is sufficient to explain the simulated lee cyclones, despite some support for these mechanisms from case studies and statistical investigations.

It thus appears that a unique mechanism for lee cyclogenesis does not exist. Rather lee cyclogenesis derives from a combination of different factors, with relative contributions that vary from mountain to mountain and case to case.

Nevertheless, the blocking of low-level cold air in combination with upper-level PV advection appears to play at least some role in most of the cases. This mechanism is well compatible with the classical cyclogenesis theory in absence of topography, and applicable to many mountain ranges, among them the Alps and the Rocky Mountains. It is interesting to note that as early as 1920, orographic blocking and cold frontal retardation was mooted by the Austrian meteorologist Heinrich von Ficker as being the likely explanation for Alpine lee cyclogenesis. In the 1950s, the mechanism was revived by case studies, and in the early 1970s by the first numerical modeling work on the subject.

Valley Winds

D Zardi, University of Trento, Trento, Italy

© 2015 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by J. Egger, volume 6, pp 2481–2490, © 2003, Elsevier Ltd.

Synopsis

The article reviews the distinctive properties of daily periodic, thermally driven winds typically occurring in mountain valleys. The mechanisms leading to the development of the horizontal pressure gradients driving such winds are examined, emphasizing the basic processes involved, as well as their connections with key physical factors, such as solar radiation and topographic features. Interactions with other thermally driven winds, such as slope flows on valley sidewalls and mountain-plain circulations, are also discussed. Implications for phenomena associated with the water cycle and moist processes, as well as with air pollution transport, are also briefly outlined.

Introduction

Valley winds are daily periodic, thermally driven circulations which develop in mountain valleys under favorable synoptic conditions, i.e., clear sky and weak or absent upper ambient winds. A valley may be loosely defined as a rather elongated orographic channel, either confined between two elevated mountain ranges, or carved into a plain (such as a canyon). A valley geometry is typically marked by the processes that concurred to shape it. These may consist in earth crust modifications by tectonic movements, erosion by glacier expansion and retreat, terrain erosion and sediment deposition performed by rivers, long-term action of atmospheric factors, or various combinations of these processes. Valleys are usually open to adjacent plains, unlike closed basins – such as the Meteor Crater in Arizona, USA – which are completely surrounded by elevated walls. Typical geometrical elements of a valley include the floor and the sidewalls. Accordingly, among the various geometrical factors affecting valley winds, we will mainly refer to the valley floor width, the sidewall slope angle, and the sidewall crest height above the valley floor. Clear skies allow strong incoming shortwave radiation during daytime, as well as outgoing longwave radiation during nighttime, and thus favor both diurnal surface heating and nocturnal cooling, i.e., the required thermal forcing. In addition, weak or absent upper winds allow an unperturbed development of these flows, which will be then only controlled by the combination of surface thermal forcing and topographic features.

Valley winds typically blow up-valley during daytime, and down-valley during nighttime. These flows are actually the lower, and more evident, branches of closed circulations, with the respective upper branches flowing in the opposite directions above the sidewall ridge-top level (Figure 1). However, these upper equalizing flows, sometimes called *antiwinds*, are more difficult to detect: being unconfined by sidewalls, unlike the valley winds below, they can occur over larger widths, and comparable depths, so they usually display smaller mean speeds. Moreover, they are more directly exposed to the perturbing influence of upper ambient winds.

Basically valley winds develop as a consequence of horizontal pressure gradients between the interior of a valley and an adjacent plain. Such gradients arise because the air

temperature cycle, associated with the daytime warming and nighttime cooling of the atmosphere, in the interior of a valley, i.e., up to a height comparable with the mean sidewall crest elevation, typically displays at any level a larger amplitude than at the same level above an adjacent plain. Accordingly, as the vertical pressure distribution is to a large extent controlled by the hydrostatic balance, these different vertical thermal profiles produce horizontal valley–plain pressure gradients, which, reversing twice per day, drive up-valley winds during daytime and down-valley winds during nighttime (Figure 1).

Notice that valley winds are not the only thermally driven circulations, which may develop over complex terrain. Actually they may be viewed as one component of a whole system of interconnected diurnal winds, typically occurring, at different scales, under the same favorable synoptic situations, over major mountain ranges surrounded by plain areas. The simplest flows are *slope winds*, blowing up the sunlit inclines during daytime, and downward during nighttime. Up-slope flows are sometimes called *anabatic* winds, and down-slope flows *katabatic winds* (from the ancient Greek verbs '*anabainein*', '*going up*', and '*katabainein*', '*going down*'). In particular the word *katabatic wind* is extensively used to denote drainage winds blowing on glaciers and large ice surfaces in the polar regions (see **Mountain Meteorology: Katabatic Winds**). Such flows also occur along the sloping sidewalls of large valleys, and contribute, as shown in the following section, to the development of *valley winds*. At even larger scales, an overall organized air motion can be identified, conveying air toward the mountain range in the lower layers during daytime, and promoting a reversed flow during nighttime. These low-level flows are also accompanied by corresponding return upper winds, flowing in the opposite directions. Altogether this comprehensive system forms the so-called *mountain-plain circulation*.

Further cases of daily periodic thermally driven circulations are found in closed basins, as well as on isolated plateaus.

The present article mainly focuses on valley winds. Slope flows and mountain-plain circulations will be only briefly outlined, insofar as it is convenient for understanding their connections with valley winds. The interested reader will find an extensive treatment of all the above circulations in the review by Zardi and Whiteman (2013).

Figure 1 Idealized picture of the vertical structure associated with daytime up-valley wind (upper panel) and nighttime down-valley wind (lower panel) between a valley and an adjacent plain. The red and blue curves reproduce vertical profiles of the horizontal wind component at the valley inlet. The two columns of air – one representing of the atmosphere over the valley floor, and one above the plain – include red and blue sections, indicating layers where potential temperature is relatively warm (W) or cold (C). The free atmosphere is unperturbed by the daily cycle above the tops of the columns. Reproduced with permission from Zardi, D., Whiteman, C.D. 2013. Diurnal mountain wind systems. Being forced by the diurnal cycle of surface radiation, all of these circulations display a similar daily periodic up-and-down reversal. Nevertheless, the cycles of the various circulations occurring in the same area may be differently phased among them. Many factors may affect these phase delays, such as the varied exposure of the underlying terrain to incoming solar radiation, the different timing and amounts of sensible heat flux allowed by unequal surface properties, and the intrinsically different reaction timescales resulting from the circulation extent (timescales are typically larger for circulations encompassing larger areas).

Also, diurnal valley winds are not the only circulations that may be found in mountain valleys, where various kinds of airflows may be produced by the action of upper winds, or pressure gradients associated with synoptic scale structures, rather than from the diurnal cycle of incoming solar radiation. The former are called *dynamically driven winds*, as opposed to the *thermally driven* valley winds, which are the main subject of the present article. Indeed, as the latter are originated from the heating and cooling of the valley atmosphere via surface energy

budgets, they are not caused by upper winds blowing above the valley, which may possibly condition, but not primarily determine, their evolution and spatial structure. In fact, thermally driven diurnal wind systems are better developed when the above external forcings are weaker. This may be argued from the panels on the first row of [Figure 2](#): here the direction of valley winds is not affected by the direction of the upper geostrophic wind, and this is the only case displaying a natural diurnal cycle. In contrast, dynamically driven valley winds are clearly marked by the action of the forcing synoptic systems. Indeed three main channelling scenarios are associated with the ambient wind above the valley, and arise either from downward transport of horizontal momentum; from channelling of ambient winds by the valley sidewalls, and the consequent alignment with the valley axis; or from pressure-driven channelling. The connection between geostrophic wind direction and the resulting channelled wind in the valley is schematically shown in [Figure 2](#) for all the above cases.

The first mechanism consists in a strong downward transport of horizontal momentum from above the valley, caused

Figure 2 The relationship between above-valley (geostrophic) and valley wind directions for four possible forcing mechanisms: thermal forcing, downward momentum transport, forced channelling, and pressure-driven channelling. The valley is assumed to run from northeast to southwest. Reproduced with permission from Whiteman, C.D., Doran, J.C., 1993. The relationship between overlying synoptic-scale flows and winds within a valley. *Journal of Applied Meteorology* 32, 1669–1682.

by either turbulent mixing, gravity waves, or other mechanisms. Friction determines a slight turning of the wind from the geostrophic wind direction toward the lower pressure as the ground is approached. This coupling is most likely to occur during unstable or neutrally stratified conditions in wide valleys, with low sidewalls and flat bottom, where thermally driven winds are less likely to develop, and channelling along the valley axis by the sidewalls would be rather ineffective.

A second mechanism is known as *forced channelling*: it occurs when ambient winds, which are in geostrophic balance above the valley, are channelled by the valley sidewalls so that the wind aligns with the valley axis. In this case, the direction and speed of the valley wind depend on the sign and magnitude of the component of the ambient wind projected along the valley axis. Wind blows up or down the valley axis depending on the direction of the geostrophic wind relative to it. As a consequence, winds are predominantly aligned with the valley axis, with sudden shifts when geostrophic wind shifts across a line normal to the valley axis.

A third mechanism is *pressure-driven channelling*, which occurs when the wind in the valley is driven by the component of the geostrophic pressure gradient in the along-valley direction. This gradient will be zero only when geostrophic wind is directed along the valley axis. Winds in the valley will shift from up to down valley (or vice versa) when the geostrophic wind

direction shifts across the valley axis. Pressure-driven channelling produces winds blowing predominantly along the valley axis, as for the previous case, but the valley wind reversal occurs for geostrophic wind directions 90° different from those of the forced channelling mechanism. Notice that winds in the valley can blow in opposition to along-valley wind direction components above the valley.

The above *dynamically driven* winds may typically display strong intensities, depending on how strong the forcing synoptic situations are. In contrast, *thermally driven* valley winds generally display weak to moderate speeds. Nevertheless, some remarkable examples of strong valley winds have been observed. For instance, in the Kali Gandaki Valley in Nepal, connecting the Indian Plain to the Tibetan Plateau (Figure 3), wind speeds in the order of $5\text{--}15\text{ m s}^{-1}$ are commonly met (Figure 4). Strong and gusty wind speeds may also occur when valley winds blow through elevated rims or gaps overlooking lower lands. As an example, such a situation occurs rather regularly in spring and summertime in the Alps, at the Lakes Valley exit. The latter is shaped as an elevated saddle, opening on the steep western side of the Adige Valley, north of the city of Trento. Here the local wind known as ‘*Ora del Garda*’ – a coupled lake and valley breeze, originating from Lake Garda shores, and then channelling along the nearby Lakes Valley – outflows through the saddle, and suddenly jumps onto

Figure 3 Map of the Kali Gandaki Valley in Nepal. Dots indicate the main villages and towns. Solid lines are height contours (labeled in m AMSL). Horizontal distances are in km. the Adige Valley floor: interacting with the local up-valley wind (as suggested in Figure 5), this outflow results in a strong and gusty wind, blowing there throughout the afternoon.

The typical diurnal cycle of valley winds follows the natural sequence of daytime heating and nighttime cooling at the

Figure 5 The area north of the city of Trento where the 'Ora del Garda' wind, blowing from the Lakes Valley (A) through an elevated saddle (★), interacts with the up-valley wind blowing in the Adige Valley from south (B). Earth's surface. The basic components of the valley winds are schematized in Figure 6, along with the timing of their diurnal development. Black arrows indicate along-valley flows, whereas white arrows denote all the airflow components blowing on valley cross sections. Notice that here, for the sake of simplicity, the valley is represented by a very idealized topography, and heating is assumed to occur symmetrically on both sides of the valley. This may only occur under very particular circumstances, e.g., when the valley axis lies on the same vertical plane as the sun trajectory in the sky (such as along the equator at equinoxes), and terrain properties are symmetrically distributed on the two sides of the valley, so as to make surface energy budgets symmetrically identical as well. Also forcing from upper winds should be symmetrically acting on the two sides. These simplifying assumptions give an idea of how many factors may variously affect the spatial distribution of key variables associated with valley wind development, such as temperature, wind strength, and direction.

After sunrise (Panel A) incoming solar radiation increasingly hits the ground. In a valley, direct radiation typically starts

lighting the crests first, and then gradually reaches the valley floor. As a consequence of the energy partitioning resulting from the surface budget (which will be addressed in the following section), part of the energy input associated with solar radiation is converted into sensible heat flux, which is increasingly supplied to the air layers adjacent to the ground. On the sidewalls this heating progressively reduces the existing temperature deficit. This deficit was produced by nighttime energy loss from radiative ground cooling, and favored the development of nocturnal drainage flows down the slopes. On the contrary, as soon as the morning heating proceeds, air parcels adjacent to the sunlit slopes become warmer, and positively buoyant. As a result they promote organized upward motions conveying warmer air all along the sloping sidewalls, from the valley floor all the way up to the crest level. Here air parcels inertially rise

even above the crest level, where they cannot get heat from the ground any more. Then they either are buoyant enough to rise further and form thermals, possibly producing cumulus clouds, or, after eventually overshooting their neutral-buoyancy level, remain trapped into a horizontal return flow converging toward the valley center. Indeed this return flow is part of a compensating circulation bringing air parcels downward to the floor level, where air is diverted toward the sidewall feet to feed slope flows. This circulation contributes, along with heat locally supplied by energy partitioning at the valley floor, to remove the nocturnal stable layer on the floor, and thus to break up the ground-based nocturnal inversion, which was built up by the nighttime drainage of cold air down the sidewalls. Moreover, subsidence at the valley core produces an adiabatic compression of air parcels, and hence further contributes to raising air

temperature within the valley atmosphere. As a consequence, the overall temperature drop, and the associated density excess, produced by nocturnal cooling, are gradually overcome during the morning, as heat is increasingly supplied to the valley atmosphere. Similar processes are produced by incoming radiation over the adjacent plain, where daytime heating removes the ground-based nocturnal inversion and raises surface temperatures high enough to eventually trigger the development of atmospheric convection. However, the heating processes in the valley are quite different from those occurring on the plain. In particular, the organized circulation activated by sidewall slopes on each valley cross section is more effective in promoting a vertical heat transfer than random convective motions developing over the adjacent plain. As a consequence, at any height air temperatures throughout the valley volume are generally higher than over the plain. This contrast, increasing during the course of the day, produces a progressive reversal of the along-valley pressure gradient, and hence a reversal of the winds from down- to up-valley (Panel B). Indeed, the higher the sun over the horizon, the larger the sunlit portions of the sidewalls, and the stronger the incoming radiation per unit surface area. Accordingly, the intensity of along-valley winds typically reaches a maximum by mid-afternoon (Panel C). The strength of up-valley winds may even overwhelm slope winds, which may get increasingly embedded in them (Panel D). As soon as solar radiation starts declining, slope winds progressively weaken as well: indeed the energy input from declining solar radiation can no longer compensate the longwave net radiative loss. As a consequence, the sensible heat flux to the air layers adjacent to the slopes becomes negative, and a cooling phase begins, resulting in a progressive reversal of slope winds (Panel E). The slope winds then act as drainage flows, bringing colder air along the sidewalls to the valley floor, and thus contributing to an overall cooling of the valley atmosphere. The up-valley wind inertially continues blowing for some time after sunset, and thus maintains a residual mechanical turbulence production in the surface layer, which favors turbulent mixing and thus sustains sensible heat fluxes. Such a circulation promotes a rather efficient overall cooling of the valley atmosphere, whose lower layers rapidly become colder than the layers at equal heights above the adjacent plain. This contrast leads to a gradual reversal of the daytime plain–valley horizontal pressure gradient, and accordingly to a weakening of the up-valley wind (Panel F), and then, finally, to the onset of a down-valley wind (Panel G). This wind typically blows stronger and stronger, and in increasingly deeper layers, during the course of the night (Panel H). The resulting nocturnal circulation is maintained by the combination of cooling processes, favored by outgoing radiation and advection of colder air, which keep operating till dawn, when the cycle starts again from the beginning (Panel A).

As a result of these alternating slope and valley winds, at any point on a valley sidewall the surface wind vector displays a typical rotation during the day, as shown in Figure 7.

As implied in the above description, as far as a valley shape and layout are similar to the idealized topography reproduced in Figure 6, the main stream of the valley wind will ideally follow the along-valley axis. However, a variety of modifications in space and time – such as accelerations and decelerations, deviations, secondary circulations, bifurcations, and

confluences – may occur in connection with changes in topographic factors – such as valley cross-section area, or shape, or valley curvatures. Further modifications may derive from varied surface properties, or from interactions with concurring winds flowing along tributary valleys, as well as from changes in the external forcings, such as the varying intensity of solar radiation at the ground in space and time, or the changing action of upper winds. A full account of these effects cannot be provided here: the interested reader will find further details and literature references to various case studies in the mentioned chapter by Zardi and Whiteman (2013).

It is interesting to observe that the development of valley winds displays many analogies with the development of coastal breezes (see **Mountain Meteorology: Land and Sea Breezes**). The latter are daily periodic wind systems blowing normal to the shorelines of seas or large lakes, under the same weather situations that favor the development of valley winds. Coastal flows are produced by horizontal pressure gradients associated with the different vertical thermal structures developing over the land and over the water surface. As these contrasts occur, with opposite results, both under the daytime heating, and under the nocturnal cooling phase, they produce coastal breezes in much the same way as valley winds are produced by valley–plain contrasts, reversing twice per day.

In particular, the overall structure of both wind systems may be viewed as an organized, large-scale solenoidal vortex, rotating in such a way that its lower branch blows from the plain to the valley interior – or, respectively, from above the sea toward the onshore region – after sunrise, and gradually reverses after sunset. Indeed such circulation, as well as the associated flow vorticity, is produced by baroclinic effects, i.e., from the misalignment of pressure and density gradients associated with the above mentioned thermal contrasts (see **Air Sea Interactions: Freshwater Flux; Momentum, Heat, and Vapor Fluxes; Sea Surface Temperature; Surface Waves. Dynamical Meteorology: Vorticity**).

Physical Processes Controlling Valley Winds

In the previous section, we outlined the basic features of a typical diurnal valley wind system, providing an intuitive insight in the combination of the physical factors concurring in its development. In the present section, we will explore in more detail some of the above processes, and the mechanisms involving them, along with the factors controlling their occurrence, intensity, and duration.

Radiation and Energy Budgets

In general, thermally forced flows are driven by buoyancy effects and pressure gradients arising from air density variations associated with heating or cooling of air parcels. On the other hand, local changes in air temperature result from a combination of factors, as clearly summarized in the tendency equation for potential temperature at any point in the atmosphere:

$$\frac{\partial}{\partial t}(c_p \bar{\theta}) = -\nabla \cdot \mathbf{A} - \nabla \cdot \mathbf{H} - \frac{\bar{\theta}}{\bar{T}}(\nabla \cdot \mathbf{R} + \dot{Q}) \quad [1]$$

Here c_p is the air specific heat at constant pressure, while $\bar{\rho}$, $\bar{T}$, and $\bar{\theta}$ are the average values (with respect to turbulent

Figure 7 Diurnal rotation of the wind velocity vector resulting from the combination of slope and valley winds. Green arrows denote the velocity vector at the indicated hours, whereas red circle arrows represent the wind rotation. fluctuations) of air density, temperature, and potential temperature, respectively. The term $A = c_p \bar{\rho} \bar{u} \bar{\theta}$ is the sensible heat flux associated with advection by the mean wind velocity $\bar{u}$, $H = c_p \bar{\rho} \overline{u' \theta'}$ is the turbulent sensible heat flux (produced by the coupling between turbulent fluctuations of wind velocity u' and potential temperature θ'). (Following Reynolds decomposition for turbulent flows, primed variables indicate turbulent fluctuations with respect to the mean values, indicated by an overbar.) R is the radiative heat flux, including both the shortwave and the longwave component. Finally, $\bar{Q}$ includes the rates of heating (or cooling) associated with conversion of water vapor into or from liquid water or ice.

Notice that both advective and turbulent heat fluxes imply some air motions, i.e., respectively, a mean wind velocity $\bar{u}$ and turbulent velocity fluctuations u' . However, in the ideal situations for thermally driven flows, i.e., dry atmosphere under clear sky and calm synoptic winds, little or no advection is produced by any large scale flows, and little turbulence can be produced mechanically, i.e., through the typical energy cascade from large to small eddies, via the coupling between mean wind shear and turbulent momentum fluxes. Rather, advection and turbulence are mainly associated with air motions originated by the combination of gravity with unbalanced density gradients, produced by heating or cooling. However, these heating and cooling are not primarily induced by the absorption or emission of radiation (the term $\nabla \cdot R$ in eqn [1]), which is usually negligible within the layers involved in valley winds systems. Rather they come from processes controlling energy partitioning at the surface. Typically, the surface energy budget may be expressed in terms of the components normal to the surface (labeled with 's') of the above mentioned fluxes, i.e., radiation flux R_s , and sensible heat flux H_s , along with latent heat flux L_s , and heat flux exchanged with subsurface layers, i.e., the ground heat flux G_s , as

$$R_s + H_s + L_s + G_s = 0 \quad [2]$$

In eqn [2] all fluxes toward the surface (both from the atmosphere and from ground) are positive, and all fluxes away from the surface are negative. The turbulent latent heat flux L_s is associated with evaporation (sublimation) from, or condensation (deposition) onto, the surface. It is produced by the coupling between turbulent fluctuations of the wind velocity component normal to the surface w' and specific humidity q' , i.e., $L_s = (\ell_i \bar{\rho} \overline{w' q'})_s$, ℓ_i being the appropriate latent heat (i.e., the latent heat of vaporization ℓ_v or the latent heat of sublimation ℓ_s depending on the situation) (see **Dynamical Meteorology: Acoustic Waves**). Ground heat flux depends on heat conduction in the subsurface ground (soil, rock, etc.).

The (net all-wave) surface radiation flux R_s may be decomposed into four components, namely

$$R_s = K\uparrow + K\downarrow + L\uparrow + L\downarrow \quad [3]$$

with $K\downarrow$ being the incoming shortwave radiation, including both direct and diffuse solar radiation, $K\uparrow$ the outgoing shortwave radiation (i.e., the fraction of incoming shortwave radiation reflected by the surface), $L\uparrow$ the outgoing longwave radiation emitted by the surface, and $L\downarrow$ the incoming longwave radiation emitted downward by the atmosphere (air gases, water vapor, and clouds). Such a budget occurs at any point of the ground surface. However, over complex terrain it typically displays a higher variability in space and time, following topographic effects on incoming solar radiation. A remarkable example of a typical diurnal cycle of incoming shortwave radiation in a valley is shown in Figure 8, where mean diurnal cycles are shown from measurements performed at different points in the Riviera Valley in the Swiss Alps (Figure 9).

Therefore the surface energy budget is the main factor controlling thermally driven circulations, promoting both the turbulent heat fluxes and the advective motions required to develop the whole system of valley winds. Accordingly, factors controlling this budget also affect the development of valley winds. For instance, clear skies and clean air favor

Figure 8 Diurnal cycles of incoming short-wave radiation at different measurements sites in the Riviera Valley, Switzerland (see Figure 9 for location), namely CVF (filled dots), ESM (dashed line), ESF2 (full line), and ESR (triangles). Panels (a) and (b) represent average values during valley wind days on slope-parallel and horizontal surfaces, respectively, while panel (c) refers to overcast days. The bold curve in (b) denotes the mean diurnal cycle of extraterrestrial irradiance on a horizontal surface at site CVF. Note the different vertical axes. stronger energy exchanges, allowing elevated values of incoming solar radiation at surface level during daytime, as well as outgoing radiation emitted from the ground during nighttime. Hence such conditions favor both daytime heating and nighttime cooling of air layers at the earth surface. However, this heating or cooling depends on the energy budgets (eqns [2] and [3]), whose terms are controlled by soil properties – such as heat capacity, thermal conductivity, and moisture content – as well as by surface properties, such as reflectivity, emissivity, and topographic features. As a consequence, the strongest diurnal wind systems are typically found in elevated and dry environments: elevation provides a better exposure to solar radiation during the day, and strong longwave radiative loss at night, whereas dryness typically reduces shortwave attenuation from air turbidity and cloud cover, as well as the latent heat flux involved in water evaporation or condensation, thus allowing more energy excess (or deficit) to be available for more intense heating (or cooling) of the atmosphere.

Slope Winds

The picture of the diurnal cycle provided in Section Introduction suggests that slope flows along the valley sidewalls play a key role in the development of valley winds, as they are the earliest drivers of the whole valley wind system. Indeed, by reacting quickly to changes in the surface energy budget, following the radiation cycle at the ground, slope flows effectively promote heat and mass advection along the slopes, thus producing exchanges both in the vertical and in the cross-valley directions. As these exchanges are determined by the topographic features of the valley cross section, they occur in a much more organized way than the analogue vertical exchange processes over flat terrain: here during daytime thermal convection feeds stochastically generated thermals, resulting in an increasingly deep convective boundary layer (CBL), whereas nocturnal cooling leads to a largely uniform, increasingly stable boundary layer.

To understand the basic dynamics implied in slope flows, it is worth recalling here a prototypal model proposed by Prandtl (1942). (Strictly speaking, the original Prandtl theory accounts for a momentum flux dominated by molecular viscosity and a heat flux determined by heat conduction, i.e., for a laminar atmospheric flow. Here we propose a straightforward extension of the theory to the turbulent case, which is more likely to occur in a real atmosphere. The mathematical expression of the solution remain in fact the same, if molecular viscosity and heat diffusivity are replaced by their respective turbulent analogs, provided that they may be assumed to be constant.) Indeed let us consider an infinite plane surface tilted by an angle α over the horizontal (Figure 10), and an overlying stably stratified atmosphere, initially at rest and displaying a constant vertical potential temperature lapse rate γ . Then imagine perturbing this static equilibrium situation by imposing a prescribed constant value ΔT_s for the temperature anomaly at any point of the surface (or, equivalently, a prescribed value H_s of the sensible heat flux). Let us adopt for convenience a frame of reference, where s is the coordinate along the slope (positive up-slope) and n is the coordinate normal to the slope (positive from the surface toward the atmosphere). As the surface temperature anomaly ΔT_s is invariant with s , let us seek for a solution that does not depend on the along-slope coordinate, but only depends on n . Mass continuity then implies that the motion be perfectly parallel to the slope, i.e., there will be only one velocity component along s (positive up-slope). Moreover, let us seek for a steady-state solution. Accordingly the equations for conservation of momentum and energy at leading order reduce to:

$$0 = \beta g \sin \alpha \bar{\theta} - \frac{\partial}{\partial n} \overline{u' w'} \quad [4]$$

$$\gamma \sin \alpha \bar{u} = - \frac{\partial}{\partial n} \overline{w' \theta'} \quad [5]$$

Equation [4] represents the local balance between two forces (per unit mass). The first term represents the buoyancy force, resulting from the combination of gravity (g), topography (α), and the relative density anomaly, represented by $\beta \bar{\theta}$, where β is the coefficient of thermal expansion and $\bar{\theta}$ is the potential temperature anomaly with respect to the

unperturbed situation. This term produces a positive (up-slope) buoyancy force on lighter parcels (i.e., parcels displaying a larger potential temperature than at the same level in the unperturbed atmosphere) and vice versa. The second term represents friction effects, produced by turbulent momentum flux in the direction normal to the slope. Friction always counteracts air motions, either up-slope or down-slope, and a steady motion requires that buoyancy and friction permanently balance each other.

Equation [5] represents a local energy balance between along-slope heat advection and sensible heat flux normal to the slope. For positive $\bar{u}$ the first term reproduces an up-slope advection of potentially colder air from lower layers, thus contributing to local cooling. The second term is positive when heat flows from the surface to the atmosphere, which occurs when the surface displays a higher temperature than the overlying atmosphere layers. A similar reasoning applies, simply reversing the signs, for down-slope flows associated with surface cooling. The balance between the two requires that the wind blows up-slope on a surface which is heating the atmosphere, and down-slope when it is cooling.

To make progress toward a solution of eqns [4] and [5] we need to specify the structure of turbulent fluxes, or at least to stipulate a relationship between them and the unknown variables $\bar{u}$ and $\bar{\theta}$. One way is to postulate that turbulent transport processes behave in a similar way to their molecular analogs, such as viscous friction or heat conduction, where fluxes of momentum or heat are proportional to velocity and temperature gradients, respectively. So let us set:

$$\overline{u'w'} = -K_m \frac{\partial \bar{u}}{\partial n} \quad [6]$$

$$\overline{w'\theta'} = -K_h \frac{\partial \bar{\theta}}{\partial n} \quad [7]$$

where K_m and K_h are the eddy viscosity and eddy heat diffusivity, respectively. Assuming further that these are constant values throughout the slope flow layer, substituting in eqns [4] and [5] one gets two coupled linear equations that admit the solution found by Prandtl (1942):

$$\bar{u} = U \exp(-n/\ell) \sin(n/\ell) \quad [8]$$

$$\bar{\theta} = \Delta T_s \exp(-n/\ell) \cos(n/\ell) \quad [9]$$

where $U = N\gamma^{-1}Pr_T^{-1/2}\Delta T_s$, with $N = (\beta g\gamma)^{1/2}$ being the Brunt-Vaisala frequency of the unperturbed atmosphere and $Pr_T = K_m/K_h$ the turbulent Prandtl number.

The length scale ℓ is provided by:

$$\ell = \left(\frac{4K_h K_m}{N^2 \sin^2 \alpha} \right)^{1/4} \quad [10]$$

An example of the slope-normal profiles provided by this solution is shown in Figure 10. The potential temperature anomaly is maximum at the surface, and then its magnitude decreases exponentially with distance from the surface, reversing sign at the nodes of the cosine function. This means that some upper counterflow accompanies the development of the main flow adjacent to the surface. Indeed, as a result of friction, due to the thermal upward thrust, layers which have not themselves been heated are set in motion, so after they have risen to a new position they are colder than the particles which were there, when the stratification of the air was undisturbed. The wind strength scale U is proportional to the surface temperature anomaly ΔT_s : therefore a large, positive ΔT_s produces a strong up-slope flow, and vice versa. Figure 10 also shows how potential-isothermal lines are modified by the

Figure 11 Velocity profiles from observations (curves B) performed with pilot balloons on the Nordkette (near Innsbruck, Austria) and theoretical predictions (curves T) based on Prandtl's (1942) model for up-slope (a) and down-slope (b) winds. Dashed lines indicate the difference between observed and theoretically calculated wind speed above the maximum. slope flow: far from the surface the isolines are perfectly horizontal and equally spaced, reflecting the constant vertical lapse rate of potential temperature in the unperturbed atmosphere. Closer to the surface, isolines bend downward for a heated surface, associated with up-slope flow, and upward for a cooling surface, associated with down-slope flows.

The above theoretical model explains many aspects involved in the development of slope flows, and despite many idealizing assumptions (infinite plane slope, s -invariance) and approximations (linearization, simplified representation of turbulence), it captures the essentials of real slope winds, as shown by measurements taken on real slopes reported in Figure 11. The main discrepancies appear in up-slope flows, where measurements suggest a deeper layer characterized by upward velocity than estimated by the model profile. This has probably to do with the stronger upward convective motions associated with thermally generated turbulence. This idea is also supported by high-resolution numerical simulations. Figure 12 shows slope-normal profiles of along-slope wind speed and potential temperature anomaly from large eddy simulations of steady turbulent up-slope flow over an infinite slope for various slope angles ($\alpha = 2, 4, 7, 10$, and 30°). Both velocity and temperature profiles display some similarities with Prandtl's solutions. However, for angles $\alpha \leq 10^\circ$ a well-mixed layer develops, which makes potential temperature uniform for a significant depth above the surface layer, and also makes the velocity profiles rather flat.

Further results for realistic cases of down-slope flows are not reported here, as they are the subject of the article **Mountain Meteorology: Katabatic Winds** in this Encyclopedia.

Turbulence

As envisaged in the previous section, turbulent motions play a key role in enhancing momentum and energy exchanges in thermally driven flows. As discussed before, the main forcing for valley winds comes from energy and momentum exchanges at the surface, where flows are inherently turbulent, and this implies that these exchanges are stronger where turbulence is more intense. A measure of the turbulence intensity is provided by the turbulent kinetic energy (TKE). TKE is defined as the kinetic energy per unit mass associated with the turbulent velocity fluctuations, namely $TKE = \overline{u'^2} + \overline{v'^2} + \overline{w'^2}$, where u , v , and w are the velocity components with respect to some Cartesian coordinate system and an overbar denotes the average with respect to turbulence. The two main mechanisms controlling the production of TKE are the so-called *mechanical production*, arising from the coupling of momentum flux with the gradient of the mean flow, and *buoyancy production*, originated by the coupling of buoyancy flux with background stratification. While the former is always positive, i.e., always contributes to increasing TKE, the latter is positive under unstable conditions, whereas it acts to suppress turbulence under stable situations. Figure 13 shows the spatial distribution of (subgrid) TKE obtained with large eddy simulations on a valley cross section of two idealized valleys – a wider and a narrower one – at two different times, i.e., at 13 p.m. (upper panels) and at 17 p.m. (lower panels). During daytime surface heating continuously feeds buoyancy production of TKE, which is then redistributed either by larger thermals,

Figure 12 Profiles of mean velocity (left) and temperature (right) from Large-Eddy Simulations of turbulent up-slope flows for inclination angles $\alpha = 2, 4, 7, 10$, and 30° . Mean wind speed $\langle u \rangle$, temperature $\langle T \rangle$, and height above the slope n are normalized by the following scales: $v_* = (\beta g H_s / N)^{1/2}$, $H = v_* / N$, and $\theta_* = H_s / v_*$. With the setting adopted for the simulations ($\gamma = 0.003 \text{ K m}^{-1}$, $\beta = 1/300 \text{ K}^{-1}$, $g = 10 \text{ m s}^{-2}$, and $H_s = 0.1 \text{ K m s}^{-1}$) the scale values result in $v_* = 0.58 \text{ m s}^{-1}$, $H = 58 \text{ m}$, and $\theta_* = 0.17 \text{ K}$. The error bars signify standard deviations. The thin line in the panel on the right corresponds to the well-mixed situation. Reproduced with permission from Schumann, 1990. Large-eddy simulation of the up-slope boundary layer. Quarterly Journal of the Royal Meteorological Society 116, 637–670.

Figure 13 Consecutive mid-domain cross sections of θ (isolines every 0.2 K, thick every 1 K; $\theta = 312$ K at top) and subgrid-scale TKE (shading) in the (left) narrow and (right) wide valley runs. Subgrid-scale TKE, approximately one order of magnitude smaller than the explicitly resolved fraction, is used merely to suggest the position of the dominant turbulent eddies. especially above the valley floor of a wide valley, or by the combined effect of slope flows and the resulting cross-valley circulation. These two processes realize a sort of competition between a more organized flow, marked by orographic features of the terrain, and randomly generated thermals on the valley floor, more similar to those typically forming on openly flat terrain. As a consequence, in a narrow valley slope

Figure 14 An idealized sketch of the cross-valley circulation induced by up-slope flows (1) ending in thermal plumes (2) at the crest tops, and in horizontal motions (3) at mountaintop level. Adiabatic subsidence (4) stabilizes the valley core, and suppresses the development of a convective boundary layer (5) on the valley floor. Figure 15 Comparison of potential temperature profiles over a plain (dashed black line, about 8 h after sunrise), wide valley (gray line, 7 h after sunrise), and narrow valley (continuous black line, 7 h after sunrise). The cross sections of the two valleys are the same as in Figure 13. The different times correspond to an equal energy input for all cases. The horizontal gray line indicates the level of the top of the valley sidewall. Reproduced with permission from Serafin, S., Zardi, D., 2011. Daytime development of the boundary layer over a plain and in a valley under fair weather conditions: a comparison by means of idealized numerical simulations. *Journal of Atmospheric Science* 68, 2128–2141.

flows are expected to be stronger, and thermal plumes on the sidewall crests more developed, than in a wider one.

Vertical Thermal Structure and Horizontal Pressure Gradients

The main mechanism driving valley winds originates from pressure unbalances arising at various levels between neighboring regions – namely within a valley and above an adjacent plain – as a consequence of different processes producing air heating or cooling at different levels in the two regions. The processes leading to these contrasts can be better understood by considering again an ideal valley–plain system, consisting of a simple valley with an along-valley invariant, symmetric cross section, and a horizontal floor, facing an open plain. Vertical accelerations associated with either upward or downward motions characterizing valley winds are usually small. Therefore, the vertical pressure distribution is essentially governed by hydrostatic balance. Hence horizontal pressure gradients, driving along valley flows, arise just from changes in the vertical temperature distribution occurring during the diurnal cycle in the valley atmosphere and in the adjacent plains.

To point out the relationship between the vertical thermal structure and the along-valley pressure gradient, consider a valley with a perfectly horizontal floor at the same level as the adjacent plain. Let us concentrate on the along-valley pressure distribution considering the values that pressure assumes over a vertical plane based on the along-valley axis at the valley floor. Also, let us focus on the daytime phase, as similar reasoning may be easily extended by analogy to the nighttime phase.

The mechanisms leading to the heating of the valley atmosphere over a vertical cross section are schematized in Figure 14. Up-slope flows along the sidewalls convey heated air up to the crest level, where it either produces vertically ascending thermal plumes, or gets involved in the upper return flow converging toward the valley center and feeding the subsidence motion that compensates the removal of heated air operated by up-slope flows at lower levels. These mechanisms result in a vertical thermal structure, which is remarkably different from the classical CBL profile occurring under the same weather situation and solar radiation over a plain. Figures 15 and 16 offer a comparison between the two situations, and some hints about the influence of the valley width. The vertical structure of the CBL in

Figure 16 Daytime development of the vertical profiles of temperature and pressure differences, taken at the same heights, between the interior of an idealized valley and an adjacent plain region. Two cases are considered, representative of a narrow and a large valley (the two valley cross sections are the same as in Figure 13). Upper panels refer to the narrow valley and lower panels to the larger one. In all frames, profiles evolve in time from an unperturbed state (representative of sunrise time), where the atmosphere has the same vertical structure both in the valley and in the plain (light gray), to a final condition (12 h later) where the contrasts between the valleys and the plains are largest (black). Reproduced with permission from Serafin, S., Zardi, D., 2011. Daytime development of the boundary layer over a plain and in a valley under fair weather conditions: a comparison by means of idealized numerical simulations. *Journal of Atmospheric Science* 68, 2128–2141.

a valley displays a shallower mixed layer, topped by a deeper stable layer. The valley atmosphere is potentially warmer than over the plain throughout the depth of the boundary layer. Also, under the same forcing, the narrow valley produces a warmer atmosphere than the wider one. There are two main reasons: slope flows at the valley sidewalls promote the intake of air at the sidewall feet, and thus remove newly heated air from above the valley floor, subtracting it from getting involved in the development of the CBL. However, the wider the valley, the smaller the mean air intake per unit valley width, so this process is more effective on a narrow valley floor. As a consequence the mixed layer that develops over the valley floor is generally shallower than over a plain, and this aspect is more evident in the narrow valley. The reason consists in the fact that slope flows along the sidewalls develop almost identically in both valleys, but their effect on the core of the valley atmosphere depends on the valley cross-section aspect ratio: the larger the valley, the weaker the impact. Indeed the diversion of air from the valley toward the slope feet has less effect on a wider valley, so surface sensible heat flux can develop a CBL, which is more similar to that over a flat plain. On the other hand, the same air masses set in motion by slope flows feed the compensating subsidence at the valley top. However, mass conservation requires that the downward velocity of this sinking motion be inversely proportional to the valley width, so a weaker subsidence occurs in a wider valley.

All of these processes result in valley–plain contrasts in the vertical profiles of temperature and pressure, which are well summarized for an idealized valley case in [Figure 16](#) (see caption for explanation). Similar contrasts are also observed in real cases: [Figure 17](#) shows such a situation observed in temperature profiles from radiosoundings taken respectively at Innsbruck, in the upper Inn Valley in the Alps, and at Munich, in the adjacent Bavarian Plain.

The effect of such contrasting vertical structures on the winds is also clearly exemplified by the diurnal cycle observed in the Adige Valley, on the southern side of the Alps, facing the adjacent Po Plain ([Figure 18](#)). This valley displays a gradually sloping floor along the 150 km path connecting the surroundings of the city of Verona (91 m above mean sea level, AMSL) in

Figure 17 Vertical profiles of potential temperature from radiosoundings at Munich in the Bavarian plain (dotted line) at 519 m AMSL, and Innsbruck in the Inn Valley (solid line) at 574 m MSL, at 1200 UTC 19 July 2002. From Weissmann, et al., 2005. The Alpine mountain–plain circulation: airborne Doppler lidar measurements and numerical simulations. *Monthly Weather Review* 133, 3095–3109.

the plain to the upper valley at Merano (330 m AMSL). Results reproduced in [Figures 19–21](#) report averaged values for all the days in which favorable weather conditions allowed a full development of valley winds in the years 2004–11. In particular, [Figure 19](#) shows diurnal mean cycles of along-valley wind speed at various stations along the valley. Amplitude and phase of local wind strength are strongly affected by local topography and land cover. Nevertheless the typical cycle of daytime up-valley wind, peaking in the afternoon, and down-valley nocturnal winds, weaker but persisting throughout the night, is clearly reproduced at all the stations. As already pointed out, this diurnal wind cycle occurs in connection with the corresponding cycle of horizontal pressure distribution. This connection is shown by the mean diurnal oscillation of surface pressure at various stations along the valley, from the plain (Verona) to the upper valley (Merano), reproduced in [Figure 20](#). Notice that the amplitude of the diurnal surface pressure cycle displays an increasing trend up-valley, with the smallest value in Verona and the largest in Merano. As a consequence the along-valley pressure distribution displays the layout shown in [Figure 21](#). The pressure change with along-valley distance from the plain is almost linear at any time. However, the higher amplitudes occurring further up-valley cause a daily periodic reversal of the pressure gradient.

Figure 21 Average diurnal development of the surface pressure deviation (time LST in the chart). The slope of the curves gives an idea of the local horizontal pressure gradient along the valley. Courtesy L. Giovannini.

Similar pressure cycles occur at all levels within the layer affected by valley winds, and are the main drivers of the daily alternating wind strength and direction at any level. The vertical structure of these winds is strongly dependent on local

Figure 22 Vertical velocity profiles of down-valley winds normalized with the wind speed at the jet maximum u_m for the days 18, 20, 26, and 30 September 1984 in the Brush Creek Valley (Colorado). The solid line is a least-square fit of the expression $u(z)/u_m = A \exp(-Bz) \sin(\pi z/D)$, resulting in $A = 3.2$ and $B = 3.3$ m. Reproduced with permission from Clements, et al., 1989. Mean structure of the nocturnal drainage flow in a deep valley. *Journal of Applied Meteorology* 28, 457–462.

topographic features (curvatures, valley width changes, etc.), as well as on the strength and timing of the various forcing terms. As a consequence a generally valid shape for valley wind profiles, as schematized in Figure 1, cannot be easily provided. However, in some cases vertical profiles inspired by Prandtl's (1942) solution for slope flows successfully reproduced observations, as shown in Figure 22 for along-valley wind measurements in the Brush Creek Valley.

Interactions with Mountain-Plain Circulations

Daily periodic winds occurring along valleys lying in the major mountain ranges (such as the Alps, the Rocky Mountains, the Himalayan Chain, and Tibetan Plateau) are often embedded within the associated larger scale mountain-plain circulations, embracing the whole extent of the mountain range. Mountain-plain circulations are also driven by a diurnal pressure oscillation between the mountainous region and the adjacent plains. For the largest mountains, these oscillations have been observed to affect one or more modes of the atmospheric tides at global scale. The daily periodic reversal of this wind system is somewhat delayed relative to slope and valley winds because of the larger air mass involved.

Based on extensive numerical model simulations on a targeted area East of the Rocky Mountains, Wolyn and McKee (1994) identified a conceptual model of the daytime evolution of the mountain-plain circulation, which includes a sunrise state and three phases (Figure 23). The main features of the sunrise state are the bulging isentropes, the jet down the east side of the barrier and the stable core (Panel A). Divergence created by the nocturnal flows helps create the downward bulging isentropes. Phase 1 (Panel B) results from the weakening nocturnal flows interacting with surface heating, and lasts until 3–4 h after sunrise. Warming is associated with the weakening nocturnal jets, and occurs up to 20 km east of the

Figure 23 Conceptual daytime mountain-plain circulation model: (a) sunrise state, in which there is an interaction between nocturnal thermal and ambient flows; (b) phase 1, during which the weakening nocturnal flow interacts with surface heating; (c–d) phase 2, consisting of the developing solenoid; and (e) phase 3, the migrating solenoid. Further details are discussed in the text. Reproduced with permission from Zhang, Koch, 2000. Numerical simulations of a gravity wave event over CCOPE. barrier base. Panel C shows the first stage of phase 2, characterized by a developing solenoidal circulation. The CBL on the eastern plains is suppressed due to horizontal cold-air advection in the CBL and the warming above the CBL. In stage 2 (Panel D) sinking and horizontal warm-air advection immediately east of the solenoid center warms the air sufficiently to create a negative pressure gradient (lower to the west) in the stable core above the CBL. This region of negative pressure

gradient expands eastward, and the reversal from negative to positive of the horizontal pressure gradient is marked by a pressure ridge: when this pressure ridge passes over a site, easterly flows appear above the CBL, strong vertical wind shear develops in the region between the strengthening up-slope and the westerly return flows, and the westward mass flux in the up-slope flow increases at a faster rate. Phase 3 (Panel E) is characterized by a migrating solenoid, whose center is located in

a pressure trough beneath the eastward-moving leading edge of the cold core. The migrating solenoid is only a transient disturbance: the main daytime circulation remains nearly stationary during this phase. Generally when the solenoid passes a location, the CBL grows explosively and the depth of the up-slope flow increases.

Atmospheric Processes Affected by Daily Periodic Mountain and Valley Winds

A variety of atmospheric processes may be affected by the diurnal cycle of valley winds. Here we concentrate on two aspects, namely processes involving water and those affecting air quality.

Water Cycle and Moist Processes

The dynamics of valley winds involve essentially dry processes. Nonetheless many valleys lie near, or contain, water bodies or humid and vegetated areas. Whenever an appreciable water content is available, moist processes may significantly affect the energy and mass budgets associated with valley flows. For instance, higher contents of soil moisture affect the partitioning of surface fluxes, and tend to increase latent heat fluxes at the expense of reduced sensible heat fluxes, thus hampering the heating of surface layers. This is the reason why thermally driven circulations are best developed in arid environments.

Rising motions of moist air may eventually lead to condensation and to the formation of clouds in the upper part

Figure 24 Map (top) and 3-D perspective (bottom) of the Elqui Valley in the Andes. The dashed line in the valley is oriented along the valley axis. 'LS' and 'Vi' indicate the positions of La Serena (145 m AMSL) and Vicuña (650 m AMSL), respectively. AMSL, above mean sea level. Reproduced with permission from Bischoff-Gauß, et al., 2008. Model Simulations of the Boundary-Layer Evolution over an Arid Andes Valley. Boundary-Layer Meteorology 128, 357–379.

of valley sidewalls or above the crests. The resulting clouds may cover the sky and thus reduce the radiative energy input, and produce showers and thunderstorms, especially in the afternoon.

Nocturnal cooling by drainage winds, especially at the valley floor, may lead to condensation. The formation of dew may be beneficial as water supply to vegetation and cultures, especially in arid areas. On the other hand, frost may produce serious damage to crops, and surface icing, as well as fog, may lead to serious risks for transportation safety.

Examples of the first case are found in some valleys on the western side of the Andes range, facing the Pacific Ocean, such

as the Elqui Valley in Chile (Figure 24). Daily sums of nocturnal dew deposition by condensation of moist air, advected from the coast by daytime up-valley winds are shown in Figure 25. The annual nocturnal sum of dew deposition amounts to 5–10 mm year⁻¹, which is about 5–10% of the mean annual precipitation, but almost of the same order of magnitude as precipitation amounts in dry years. So, as in many other arid areas, dew deposition is an important additional source of water for the natural vegetation, especially in dry years.

Also, organized thermally driven vertical motions of moist air associated with valley winds, may contribute, like other

Figure 25 Daily sum of nocturnal dew deposition (D) at Pelicana and daily sum of precipitation at La Vicuña in 2000 (upper panel) and accumulated annual dew formation for 2000–02 (lower panel). combinations of thermally driven flows over complex terrain, to promote convective and orographically induced clouds, as well as the associated precipitation phenomena. Mountain-plain circulations also play a key role in moisture transport, and in the initiation of moist convection. Typically convergence of the daytime flows over the mountains produces afternoon clouds and air mass thunderstorms, and the divergent nighttime sinking motions produce late afternoon and evening clearing. A remarkable example, as to intensity and extension, is offered by the mountain-plain circulation effects on warm-season precipitation east of the Tibetan Plateau, which are strongly affected by the differential heating between the plateau, the highlands, the plains, and the ocean. **Figure 26** shows latitude-averaged vertical cross sections of typical circulation patterns associated with the diurnal cycle. In the early afternoon (**Figure 26(a)**), there are three distinct west–east solenoidal circulations in the lower- to mid-troposphere. These circulations are driven by the differential diabatic heating, with the upward branches on the highland-plateau slopes and the downward branches over the low

basins, plains, and oceans. The westernmost and strongest solenoid (S1) has the westward-tilted rising branch over the eastern slope of the Tibetan Plateau and the sinking branch over the Sichuan basin. The second solenoid in the middle (S2) has a rather shallower rising branch over the highlands along the Qinling and Wushan mountain ranges, and a more extended and broader sinking branch over the east China plains. The third solenoid (S3) has the rising branch along the coastal lands and the weak sinking branch over the nearby oceans. Each of the upward branches of the solenoids corresponds to a diurnal precipitation peak. On a larger scale there also exists a broader domain-wide vertical solenoid circulation (S0) across all three solenoids with the upward branch on the eastern Tibetan Plateau and the downward branch over the plains. In the early evening (**Figure 26(b)**), the S0 becomes the dominant mode in the cross section, with the upward motion strengthened at the eastern slope of the Tibetan Plateau and the downward motion over most of the areas eastward except for the weak upward branch of the S2 in the lower troposphere on the eastern slope of the Qinling and Wushan mountain ranges.

Figure 27 Selected pictures from the wintertime field measurements of pollutant dispersion in the Inn Valley (Austria). (a) Map of the target area: color scale represents elevations in km AMSL, yellow and red markers indicate the locations of measurement sites and towns. (b) Vertical transects of aerosol backscatter intensity at 1400 UTC 24 January 2006 (A1–A2 as in panel a). (c) Schematic of pollution transport processes by up-slope winds. Arrows indicate mean flow and turbulent eddies. A white solid (dashed) line indicates a closed (broken) snow cover. AMSL, above mean sea level. Reproduced with permission from Gohm, et al., 2009. Air Pollution Transport in an Alpine Valley: results from airborne and ground-based observations. *Boundary-Layer Meteorology* 131, 441–463.

Both the upward branches of S1 and S2 continue to be associated with local diurnal precipitation maxima at this hour, while the broader and stronger sinking branch over the east China plains corresponds to a broad local precipitation minimum phase in these regions at this hour. The coastal solenoid S3 is mostly absent in this early evening hour, though the sinking branch over the ocean is considerably stronger than over the coastal land. In the early morning (Figure 26(c)), the nighttime vertical circulation is nearly a complete reversal of the daytime circulation (Figure 26(a)) with the downward branches over the highland–plateau slopes and the upward branches over the low-lying plains–basins. Consequently, strong diurnal precipitation peaks (nocturnal rainfall maxima)

are observed over the Sichuan basin (part of S1) and over the east China plains (part of S2). However, the nocturnal circulation pattern may be further strengthened to peaked maximum at 2100 UTC: the nocturnal precipitation peak phase over the plains is also coincidental with a developing low-level southerly jet that transports more warm moist air to this area and contributes to the enhancement of nighttime precipitation. Boundary layer processes associated with the reduced turbulence diffusion due to ceased daytime heating are believed to be responsible for the development of the low-level nocturnal jet. A few hours after sunrise (Figure 26(d)), the vertical circulation evolves from the nocturnal pattern in Figure 26(c) to the daytime pattern in Figure 26(a), and is again dominated

by the domain-scale broad solenoid (S0) as a reversal of that in [Figure 26\(b\)](#) with the downward motion maximized at the eastern slope of the Tibetan Plateau and the upward motion in a broad area to its east maximized at the mid-troposphere.

Air Pollution

Airflows and thermal structures associated with valley winds may affect the fate of atmospheric pollutants in many ways. Typical sources of air pollution are settlements, infrastructures, and industrial activities mainly based at the valley floor or, even more frequently, on the adjacent plains. So up-valley winds may convey highly polluted air into the valleys, whereas down-valley winds may have a cleansing effect of polluted air at the valley exit over the plain during nighttime. On the other hand, up-slope flows may transport to upper levels either already formed primary pollutants, or precursors of secondary pollutants released at the valley floor. There the exposure to radiation may enhance the formation of photochemical species, which eventually get drained to lower levels by nocturnal down-slope winds.

Also the thermal structures associated with valley winds, through their effects on stability, may affect the fate of atmospheric pollutants. For example, the depressed CBL over the valley floor may reduce the mixing height, leading to higher concentrations. This may be particularly critical during wintertime, when on one hand the reduced radiative input leads to shallower mixed layers, and on the other hand, more pollutants are emitted from house heating and traffic. In a similar way the frequent occurrence of nighttime inversions, especially during wintertime, also reduces the mixing height.

[Figure 27](#) provides an example of nontrivial features characterizing wintertime pollutant dispersion patterns in the Inn Valley in the Alps.

Acknowledgments

Data from surface weather stations used for the graphics presented in [Figures 19–21](#) were kindly provided by the Hydrographic Office of the Autonomous Province of Bolzano (for Merano, Bolzano, Bronzolo, and Salomo stations), the Meteorological Office of the Autonomous Province of Trento – Meteotrentino (Rovereto station), the Edmund Mach Foundation (San Michele, Trento, and Ala stations), and the Environmental Agency of the Veneto Region (Verona station).

Lorenzo Giovannini kindly performed the climatological analysis of time series from the above data, and prepared [Figures 18–21](#).

The Author is greatly indebted to Massimiliano de Franceschi, Lorenzo Giovannini, Lavinia Laiti, Stefano Serafin, Elena Tomasi, and Felicity Hope for carefully reviewing the manuscript, and suggesting many valuable improvements.

Synopsis

The formulation of chemical models is discussed. This article summarizes the component modules of chemical models (gas phase chemistry, heterogeneous chemistry, photolysis, deposition). The chemical continuity equation is described. Trajectory, one-dimensional, two-dimensional, and three-dimensional models are discussed. Example applications in the stratosphere and troposphere are given.

Introduction

Chemical models are used to test our understanding of atmospheric chemistry, and for predictions of the future state of the atmosphere. A model will contain different modules to treat processes such as gas phase chemistry, aqueous phase chemistry, heterogeneous chemistry, photolysis reactions, and emission and deposition of species. The formulation of the model will depend on the problem being studied. The core of a model is the chemical continuity equation, which is an expression of the rate of change of a chemical species. Integrating this continuity equation permits the model to step forward in time. In general, the large computational cost of calculating atmospheric chemistry leads to a number of

approximations in models, such as using grouping species into families and assuming that some species are in steady state. Models that are used to study atmospheric chemistry range from zero-dimensional 'box' models, which may contain very detailed chemistry schemes (e.g., 3000 species), to global three-dimensional models, which may contain around 50.

Use of Models

Numerical models are a mathematical summary of our current understanding of atmospheric chemistry. A good model should contain a representation of all of the important species,

reactions, and processes relevant for the particular system that is being studied. A numerical model can then be used for:

- testing our understanding of atmospheric chemistry by comparison between model calculations and observations;
- investigating the effect of a newly discovered reaction or process on other species; and
- predicting the future state of the atmosphere based on a series of assumptions.

The components of the model (physical and chemical processes considered, number of chemical species and reactions) will depend on the problem being addressed (e.g., spatial and temporal scale). The model needs to have an appropriate domain (e.g., global, regional), resolution (e.g., size of grid boxes), and time step. The model must contain all of the necessary processes, but other factors (usually computer resources) often constrain those that can be included.

Components of a Chemical Model

In order to calculate the time-dependent concentrations of chemical species in the atmosphere, a model must contain a representation of the important chemical and physical processes. **Figure 1** illustrates these components and how they are used in each model time step to calculate the chemical concentrations.

Gas Phase Reactions

All models of atmospheric chemistry will deal with gas phase reactions between species (see **Chemistry of the Atmosphere: Chemical Kinetics**). Laboratory measurements provide data,

which can be used to calculate the rate constants for gas phase reactions in models. For bimolecular reactions, the rate constant usually depends only on temperature and can be calculated from the Arrhenius equation (eqn [1]), where k is the rate constant at a temperature T , A_e is the Arrhenius factor, E_a is the activation energy, and R is the gas constant. The values for A_e and E_a are provided by laboratory data.

$$k(T) = A_e \exp(-E_a/RT) \quad [1]$$

Other expressions are used to fit certain bimolecular reactions, which show a pressure dependency (e.g., $\text{HNO}_3 + \text{OH}$) and termolecular (three-body) reactions. Expert panels regularly review the body of chemical kinetics literature and produce reports of recommended rate constants for use in atmospheric models. As well as providing modelers with an expert analysis of photochemical data, their common use permits model results to be referenced and for predictions from different models to be more easily compared.

Liquid Phase Reactions

Models dealing with tropospheric chemistry will need to account for the uptake of gases by cloud droplets, and chemical reactions within the clouds (aqueous chemistry). This gas uptake and reaction involves several steps (diffusion of gas to droplet, dissolution in droplet, diffusion through droplet, reaction in droplet, diffusion of products, and evaporation of dissolved products at the droplet surface). Treating aqueous chemistry in a model is more complicated than gas phase chemistry. First, the lifetimes of aqueous species are usually short and the system of differential equations to solve is stiff (see below). Second, when dissolved species are removed by

Figure 1 Components of a chemical model. A multidimensional model will also include dynamical and radiation modules. These may be combined so that the chemistry is or is not coupled (where changes in the concentrations of chemical species feedback on the radiation and dynamics).

reactions they are rapidly replaced by dissolution of more species from the gas phase. Therefore, the processes of dissolution and chemical reaction need to be solved in a coupled way.

Heterogeneous Reactions

Heterogeneous reactions involve the collision of a gas phase molecule with a solid or liquid particle, followed by a chemical reaction. An example is the hydrolysis of N_2O_5 shown by reaction [I].

This reaction is normally parametrized in models using a measured ‘reaction probability’ (γ) that an N_2O_5 molecule colliding with a surface will react, and a ‘collision frequency’ calculated using kinetic theory and the known or assumed concentration of aerosols. This treatment can also be used for heterogeneous reactions involving solid particles. An alternative treatment for liquid aerosols, when both reactants are soluble, is to treat the reaction as a liquid phase reaction (as above).

Photolysis Rate Coefficients

The photolysis rate coefficient (or photodissociation frequency), J is the first-order rate constant for the process shown by reaction [III], where h is the Planck’s constant, and ν is the frequency of the radiation.

As solar radiation is the driving force for atmospheric chemistry, the accurate calculation of J rates is an important component of models.

The photolysis rate coefficient for species AB (J_{AB}) is calculated from eqn [2], where $I(\lambda, z)$ is the photon flux at wavelength λ and altitude z in the atmosphere, and σ is the absorption cross-section.

$$J_{\text{AB}}(z) = \int I(\lambda, z) \sigma_{\text{AB}}(\lambda) d\lambda \quad [2]$$

In an atmospheric model eqn [2] is solved by replacing the integration over wavelength by a summation over discrete wavelength intervals. The World Meteorological Organization gives a list of 158 wavelength intervals, covering the range 175–850 nm, which are typically used in stratosphere–troposphere models. Fewer wavelength intervals can be used for troposphere-only models to save computer time.

The photon flux at a point in the atmosphere, $I(\lambda, z)$, is calculated using the flux at the top of the atmosphere and the Beer–Lambert law,

$$I_{\text{tr}} = I_0 \exp(-\epsilon cl) \quad [3]$$

Where I_0 is the incident radiation, I_{tr} is the transmitted radiation, ϵ is the absorption (or extinction) coefficient, c is the concentration of the absorber, and l is the path length. The flux at altitude z depends on attenuation by absorbing gases (mainly O_2 and O_3), scattering by molecules and aerosols, and reflection by the surface and clouds.

Models may calculate an instantaneous value of J , or an average value over daylight or 24 h period. An instantaneous and regularly updated value of J is necessary for a model to

reproduce the diurnal cycle of short-lived species (e.g., OH). However, this approach can be expensive computationally. For simulations of long-lived species, where it is not necessary to explicitly resolve the diurnal cycle, day- or 24-h-averaged J rates can be used. As the interactive, online calculation of J rates is nevertheless expensive, some models use precalculated ‘lookup’ tables. The J for the required conditions is interpolated from the tabulated values.

Emissions and Physical Removal

All chemical models, except those simulating isolated air masses over short periods, require a representation of the processes that input and remove chemicals from the atmosphere. Emissions of trace gases may occur through natural (e.g., vegetation) or anthropogenic processes (e.g., industrial emissions, aircraft). Expert panels regularly review the strength of these emission sources and provide data sets for input into models (e.g., the Global Emissions Inventory Activity (GEIA) of the International Global Atmospheric Chemistry (IGAC) program). Some of these emission sources (e.g., emissions of hydrocarbons from vegetation and trace gas and aerosol emissions from wildfires) have strong spatial and temporal variability driven by climatic conditions. Biogenic emissions of trace gases such as isoprene have a strong dependence on parameters such as temperature and sunlight, and so schemes are often included in models, which represent the response of such emissions to the meteorological data being fed to the model.

Chemical species may be physically removed from the atmosphere by wet or dry deposition processes. Dry deposition removes gases and particles at air–surface interfaces. Wet deposition involves the dissolution of a gas into a cloud droplet, which is then rained out.

Chemical Continuity Equation

Chemical models aim to use the known concentrations of chemical species at time t , and calculated rates of change, to calculate the concentrations at the end of the chemical time step $t + \Delta t$. The heart of the model is a ‘chemical continuity equation.’ This is an expression for the rate of change of a chemical species due to the chemical reactions that produce or destroy it. It is an expression of the conservation of mass and can be expressed as eqn [4], where P is the rate of chemical production and L is the rate of chemical loss (which usually depends on $[\text{AB}]$), and $[\]$ indicates a concentration. Other terms can be included in eqn [4] to account for other processes that affect $[\text{AB}]$ (e.g., physical removal).

$$\frac{d[\text{AB}]}{dt} = P - L[\text{AB}] \quad [4]$$

Table 1 lists a small subset of the 100 reactions that are important in the chemistry of the stratosphere (see **Stratospheric Chemistry Topics**: Overview; Halogens; Reactive Nitrogen (NO_x and NO_y); HO_x). This subset is used here to illustrate the form of a continuity equation, but note that detailed atmospheric models will include many more species and reactions. There are three reactions in Table 1, which either produce (reaction [X]) or

Table 1 Subset of gas phase reactions important in stratospheric chemistry

$\text{Cl} + \text{O}_3 \rightarrow \text{ClO} + \text{O}_2$	[III]
$\text{ClO} + \text{O} \rightarrow \text{Cl} + \text{O}_2$	[IV]
$\text{ClO} + \text{NO} \rightarrow \text{Cl} + \text{NO}_2$	[V]
$\text{ClO} + \text{NO}_2 + \text{M} \rightarrow \text{ClONO}_2 + \text{M}$	[VI]
$\text{ClONO}_2 + h\nu \rightarrow \text{Cl} + \text{NO}_3$	[VII]
$\text{OH} + \text{HO}_2 \rightarrow \text{H}_2\text{O} + \text{O}_2$	[VIII]
$\text{O}(^1\text{D}) + \text{H}_2\text{O} \rightarrow 2\text{OH}$	[IX]
$\text{OH} + \text{NO}_2 + \text{M} \rightarrow \text{HNO}_3 + \text{M}$	[X]
$\text{OH} + \text{HNO}_3 \rightarrow \text{H}_2\text{O} + \text{NO}_3$	[XI]
$\text{HNO}_3 + h\nu \rightarrow \text{OH} + \text{NO}_2$	[XII]

destroy (reactions [XI] and [XII]) HNO_3 . Based on this reaction set, the chemical continuity equation for the rate of change of the concentration of HNO_3 contains three terms and can be represented as eqn [5],

$$\frac{d[\text{HNO}_3]}{dt} = k_X[\text{OH}][\text{NO}_2][\text{M}] - k_{\text{XI}}[\text{OH}][\text{HNO}_3] - J_{\text{XII}}[\text{HNO}_3] \quad [5]$$

where k_n is the rate constant for reaction n , J_n is the photolysis frequency, and the square brackets indicate a concentration. A continuity equation can be written for each chemical species contained in the model. This gives a set of coupled first-order ordinary differential equations. In all but the very simplest cases (e.g., the decay of a radioactive tracer), an analytical solution is not possible and the coupled differential equations must be solved numerically. This system of differential equations is usually 'stiff,' i.e., the lifetimes (or time scales) of the chemical species being solved vary by several orders of magnitude (e.g., seconds to years). Therefore, sophisticated (and computationally expensive) solvers need to be used.

A chemical continuity equation similar to [4] can be written for each species contained in the reaction scheme. However, in practice a number of conceptual simplifications and numerical approximations can be made.

Photochemical Steady State

For a chemical species with a very short chemical lifetime it is not necessary, or desirable, to integrate the chemical continuity equation. The short lifetime increases the stiffness of the system and would require a short chemical time step. Computer time can be saved by placing short-lived species in steady state.

In the chemistry of the stratosphere and troposphere, the chemical lifetime of OH is of the order minutes or less. Therefore, the concentration of OH can be derived by placing it in the photochemical (or photostationary) steady state.

Based on the reaction scheme given above, this would give eqn [6].

$$\begin{aligned} \frac{d[\text{OH}]}{dt} &= 0 \\ &= 2k_{\text{IX}}[\text{O}(^1\text{D})][\text{H}_2\text{O}] + J_{\text{XII}}[\text{HNO}_3] \\ &\quad - k_X[\text{OH}][\text{NO}_2][\text{M}] - k_{\text{XI}}[\text{OH}][\text{HNO}_3] \\ &\quad - k_{\text{VIII}}[\text{OH}][\text{HO}_2] \end{aligned} \quad [6]$$

Therefore, at each time step in the model the [OH] can be derived from the calculated concentration of other species and the appropriate rate constants and photolysis rates. The calculated concentration of OH will vary throughout the diurnal cycle (e.g., as J_{XII} changes), although at each time step the instantaneous concentration is assumed to be constant. Note that as several interdependent species may be treated to be in steady state (e.g., both [OH] and $[\text{HO}_2]$ in the above example), the steady state concentration of these species should be derived iteratively.

Chemical Families

The number of continuity equations to be solved (and computational time) can be reduced by grouping closely coupled chemical species together in a family. As well as needing to solve only one continuity equation, the photochemical lifetime of the family is generally longer than the lifetimes of the individual members, producing a less stiff system (Figure 2). Finally, using chemical families has advantages in multidimensional models. Generally, it is not desirable to transport short-lived species separately as they have strong gradients (e.g., near the terminator), which can cause numerical problems (undershoots and overshoots) in advection schemes. A chemical family will generally have a smoother distribution and pose fewer problems for the advection scheme.

In stratospheric models a ClOx family is often defined as $[\text{ClOx}] = [\text{ClO}] + [\text{Cl}]$. This is justified because Cl is in rapid

Figure 2 Photochemical lifetimes (defined as $1/(\text{first-order loss rate})$) of Cl, ClO, and ClOx ($= \text{Cl} + \text{ClO}$). The ClOx family has a much longer lifetime than the shortest lived family member, resulting in a less stiff system of equations to solve.

photochemical equilibrium with ClO, and change in the concentration of ClO will also affect Cl through the reactions, which interconvert the two. When a chemical family is used in a model, a single chemical continuity equation is written for the overall rate of change of the family. Based on the reactions given in Table 1, the continuity equation for ClOx can be expressed by eqn [7], where M represents any air molecule.

$$\begin{aligned} \frac{d[\text{ClOx}]}{dt} &= 0 \\ &= -k_{\text{VI}}[\text{ClO}][\text{NO}_2][\text{M}] + J_{\text{VII}}[\text{ClONO}_2] \end{aligned} \quad [7]$$

Note that reaction [III] for example, which simply interconverts Cl and ClO has no net effect of ClOx and does not appear in eqn [7]. The concentration of the total family must be divided among the $n - 1$ individual members. This is achieved by writing $n - 1$ steady state expressions for $n - 1$ members. In the case of the ClOx family, by placing Cl in steady state ($d[\text{Cl}]/dt = 0$) we can derive eqn [8] for the ratio of $[\text{Cl}]/[\text{ClO}]$.

$$\frac{[\text{Cl}]}{[\text{ClO}]} = \frac{k_{\text{IV}}[\text{O}] + k_{\text{V}}[\text{NO}] + J_{\text{VII}} \frac{[\text{ClONO}_2]}{[\text{ClO}]}}{k_{\text{III}}[\text{O}_3]} \quad [8]$$

Although this equation is derived by assuming Cl is in steady state, the concentration of Cl (and ClO) will vary over the model time step as ClOx changes. However, eqn [7] effectively fixes the ratio of Cl:ClO over this time step.

Care is needed when deriving these expressions for the partitioning of family members. Most of the terms in eqn [7] can be identified with reactions [III], [IV], and [V], which directly interconvert Cl and ClO. However, there is also a term involving $[\text{ClONO}_2]/[\text{ClO}]$, which is related to the two-step interconversion of ClO and Cl via the formation and photolysis of ClONO₂. It is very important to include these indirect terms as they are often associated with catalytic cycles that destroy stratospheric O₃ via the reaction [III]. In order for the model to correctly determine the O₃ loss, the calculated $[\text{Cl}]$ must be accurate.

Another chemical family commonly used in atmospheric models is 'odd oxygen,' which is defined as $\text{Ox} = \text{O}(^3\text{P}) + \text{O}(^1\text{D}) + \text{O}_3$. This family provides a very convenient way of calculating the atmospheric abundances of O₃, O(³P), and O(¹D) below about 70 km. Above this altitude the photochemical lifetime of O becomes long (due to the low air density) and so, O and O₃ can no longer be assumed to be in photochemical equilibrium.

Mechanism Reduction

The number of species and reactions involved in chemical reactions of organic species in the polluted (urban) troposphere is huge. For example, the University of Leeds Master Chemical Mechanism model contains around 3800 species and 10 000 reactions. For many practical purposes the number of reactions needs to be reduced. The methods used for reducing the number of species in urban photochemical models are: (1) the carbon-bond lumping method (when organic species are separated into a few common bond groups), (2) the surrogate species method (where species with similar reactivity are grouped together and solved as one species), and (3) the lumped species

method (where species are grouped together but the reaction rate constants for the lumped group is a mole fraction weighted average of the rate constants for the individual species).

Types of Models

A range of chemical models exists appropriate for studying different problems. In all cases the model consists essentially of a chemical 'box' model (with the description of the required chemistry) either used alone, or within an array of grid boxes in a multidimensional model.

Box Models and Trajectory Models

A chemical 'box' model solves the chemical continuity equations in a single air mass. These models can be computationally cheap, allowing detailed reaction schemes to be included (e.g., up to 500 species) and avoiding the need for numerical approximations such as chemical families. Box models can either represent a stationary, idealized air mass, or can be combined with a calculated air mass trajectory to produce a 'Lagrangian' model. Several chemical trajectory models can be integrated simultaneously to create a 'domain-filling trajectory model,' in which the number of model boxes is sufficient to fill a region of the atmosphere so that 3D distributions can be obtained.

Results from trajectory box models are generally valid over the time scale on which the approximation of no mixing into, or out of, the box is valid. This depends on the location in the atmosphere and may vary from a few days in the troposphere to a few weeks to months in the polar lower stratosphere.

Three-Dimensional Models

Three-dimensional (3D) models solve the chemistry on a longitude $\times$ latitude $\times$ altitude array of grid boxes. Dynamical processes are included that transfer chemical species between these fixed grid boxes in a so-called 'Eulerian' model. The chemical component of a 3D model is essentially a chemical box model. However, the high computational cost of a 3D model means that the reaction schemes have to be limited (e.g., to around 40–50 species) and some careful approximations used (e.g., families). The nature of 3D models, with their arrays of chemical box models, mean that they can be written to take good advantage of high performance vector and parallel computers. Nevertheless, when included in a 3D model, the cost of chemistry normally dominates the cost of other processes (e.g., radiative and dynamical calculations). Even in Earth System Models (ESMs) atmospheric chemistry is likely to be one of the most expensive components.

The chemistry and transport in a 3D model can be combined in an 'operator split' approach. In this method the chemical integration is separated from the dynamical integration and the advection of tracers. This decoupling of chemical and dynamical time steps is often more efficient as optimum time steps can be chosen for each process (e.g., the need for a short chemical time step does not imply an equally short dynamical time step). A multidimensional chemical model requires a module for

transporting chemical species – i.e., an ‘advection scheme.’ The advection scheme should ideally be: conservative, monotonic (no undershoots and overshoots), nondiffusive (maintain tracer gradients), and nondispersive (tracer features should advect independent of their scale). The advection scheme should also advect species independent of their concentration. In practice, essentially all of the tracer advection schemes in use compromise on one or more of these criteria.

Two types of 3D chemical models are commonly used. General circulation models (GCMs) are global radiative dynamical models used in numerical weather prediction and climate studies (see **Numerical Models: General Circulation Models**). Chemistry can be included in these models to produce a chemical GCM, allowing the calculation of the coupled effects of chemical and dynamical changes. In these coupled models, a chemically induced change in O_3 , for example, will affect the atmospheric heating rates, temperature, and therefore the dynamics. In turn, these dynamical changes redistribute O_3 . As GCMs calculate their own circulation, the results do not correspond to a specific day, but represent the typical behavior of the atmosphere. Therefore, the results of GCMs need to be compared with observations in a climatological sense. More recently, ESMs have been developed, which couple together processes that govern the evolution of the atmosphere, biosphere, oceans, and cryosphere. These models also contain atmospheric chemistry, and can be used to investigate potentially important Earth system feedback processes, for example between the biosphere and climate, driven by changes in atmospheric trace gas and aerosol abundances in response to changes in emissions from the biosphere.

Offline chemical transport models (CTMs) do not calculate the atmospheric circulation. Instead the wind (and temperature, humidity, cloud) fields are read in from another source (e.g., meteorological analyses). This has a number of advantages: the model is cheaper to run compared to the full GCM and, importantly, the model dynamics are constrained to the

‘real’ meteorological situation. This permits direct comparison between model calculations and observations. As the circulation in CTMs is fixed, they cannot be used for future predictions involving coupling of chemistry and dynamics. The meteorological analyses used to force CTMs come from weather services such as the European Centre for Medium-Range Weather Forecasts (ECMWF), U.K. Met Office (UKMO), or the National Centers for Environmental Prediction. They are produced as part of the routine weather prediction and now usually extend from the surface to the upper stratosphere. The accuracy of CTM results depends critically on the quality of these meteorological analyses and how they are used in the model. In the stratosphere the advection by the analyzed winds is usually the only transport process considered, while in the troposphere the model will usually need to parametrize ‘subgrid-scale’ transport processes such as convection and boundary layer mixing. **Table 2** illustrates the chemistry, which is included in a typical stratospheric CTM while **Table 3** illustrates a similar tropospheric model. The stratospheric model contains detailed halogen chemistry, while the tropospheric model contains more hydrocarbon species. Simulations of Arctic O_3 depletion from the stratospheric model are shown in **Figure 3**. **Figure 4** shows an example of CO distribution from the tropospheric model.

One-Dimensional and Two-Dimensional Models

Before computer power permitted the use of 3D chemical models one-dimensional (1D) and two-dimensional (2D) models were widely used for atmospheric studies. One-dimensional models represent variations of tracers with altitude and were the main tool in the 1970s and early 1980s. The models generally represent a global mean atmosphere at each layer and vertical motion is parametrized as a diffusion process. Clearly this is a gross approximation of the real atmosphere and these models are no longer used.

(a) SLIMCAT 3D model ozone 17 March 2000 17 km

Figure 3 Example results from the SLIMCAT three-dimensional chemical transport model (Table 2) for the Arctic winter of 1999–2000. The model was run with a horizontal resolution of 2.5° latitude × 3.75° longitude. (a) The distribution of O₃ near 17 km on 17 March 2000. The model is in good agreement with O₃ sonde observations at around 17 km (450 K potential temperature surface) at the Arctic station of Ny Alesund (78° N). (b) The difference between the model O₃ and the ‘passive’ O₃ indicates the chemical destruction since 1 January 1999. VMR, volume mixing ratio.

Two-dimensional (latitude–height) radiative dynamical chemical models calculate the zonal mean state of the atmosphere. They were the principal computational tool in the 1980–90s and are still in use. Although 2D models cannot capture the motion of stratospheric polar vortex or the longitudinal asymmetry of tropospheric surface emissions, for example, they are computationally cheap and are useful for calculating a wide range of multiyear scenarios and for sensitivity studies.

Testing Models

Given the complexities of atmospheric chemistry, and the many interactions with other processes, atmospheric chemical models can be very large programs. Much care is needed to write the code in a rigorous way to minimize the risk of errors. Generally the program should make use of all of the options available in a particular language, and on a particular machine, to test for coding errors. When a model is running it is

Figure 4 Example results from the TOMCAT three-dimensional tropospheric chemical transport model (Table 3) showing total column CO for July 2008 compared with satellite observations from the MOPPITT instrument. The model was run with a horizontal resolution of 2.8° latitude $\times$ 2.8° longitude. The upper panel shows direct model output while the lower panel shows the MOPPITT observations. The middle panel shows the model results sampled with the MOPPITT averaging kernels in order to give a true comparison of the model with the observations. CO is enhanced in regions of strong emission, such as the industrial regions of the northern hemisphere and in regions of tropical biomass burning. Figure courtesy of Sarah Monks, University of Leeds.

evaluated by comparison with observations to test its ability to capture processes in the real atmosphere. Periodically different atmospheric models are intercompared in international workshops to assess the uncertainties in model calculations due to differences in approach. The Stratospheric Processes and their Role in Climate program organized the chemistry-climate model (CCM) evaluation project CCMVal. This was an extensive process-based evaluation of the schemes in CCMs. All CCMs performed the same controlled experiments. Model output was compared against observations and against detailed 'benchmark' models. The performance of models was

graded. The overall result was an improved understanding of the models and a reduction of uncertainties in future predictions.

Synopsis

This article describes the concepts and parameterization methodologies of the major sources and sinks of heat, momentum, and constituents in the coupled ocean-atmosphere models, along with their limitations and uncertainties. The article also gives examples of the current performances of these models and discusses their major common biases.

The basis of coupled ocean-atmosphere models is a set of physical laws that govern the motion, temperature, pressure, density of the atmosphere and ocean and the concentrations of constituents in them: The Newton's second law governs the atmospheric winds and ocean currents; the first thermodynamic law describes the temperature change as a function of the heat sources and sinks; the law of mass conservation expresses the changes of concentration of various constituents as functions of their respective sources and sinks. These laws are written on a set of discretized grids and are averaged in the individual domains corresponding to this discretized set of grids. All sources and sinks of heat and constituents, and the effects of unresolved processes on the resolved scale fields, are referred to as physical processes in coupled ocean-atmosphere models. This article describes these processes. The differences in the parameterizations of these processes among the models are believed to be the main cause of differences in their simulations and predictions of weather, climate variability, and future climate change.

Radiative Transfer

Absorption and emission of radiation are internal sources and sinks of heat within the atmosphere and oceans. The wavelengths of radiation from the Sun span the range from alpha, gamma, and X-rays, to UV radiation, visible light, infrared radiation, extending to microwaves and radio waves. At the Sun's temperature of about 6000 K, the majority of the radiative energy from the Sun lies in the range from the UV to the near-infrared, with the peak in the visible lights of 0.4–0.7 μm

wavelengths. Radiation emitted from the atmosphere, the oceans, and the land surface is primarily in the range of infrared radiation with peaks in the band from 10 to 20 μm due to their lower temperatures. Because of the large difference of the temperatures of the Sun and the Earth and the separation of their respective radiation wavelength spectra, ocean-atmosphere models often calculate radiations from the Sun and from the Earth separately with different approximations as solar radiation and infrared radiation. They are also referred to as shortwave (solar) and longwave (infrared) radiations. Figure 1 shows the separation of radiation spectra from two emitting bodies of 6000 and 285 K representing the Sun and the terrestrial systems.

Radiative transfer in gases is highly sensitive to wavelengths due to the interaction of electromagnetic waves with the quantized molecular energy structure of gases. Absorption and emission of radiation differ for different types of gas molecules. Figure 2 shows portions of the absorption spectra in the shortwave for water vapor molecules and in the longwave for carbon dioxide molecules. These spectral properties are obtained from standard databases constructed from spectroscopy theory and laboratory measurements. Almost all atmospheric radiative transfer models use data from the HITRAN database (High-resolution Transmission molecular absorption database). HITRAN is a long-running project started by the Air Force Cambridge Research Laboratories in the late 1960s in response to the need for detailed knowledge of the infrared properties of the atmosphere. It has been continuously developed at the Harvard-Smithsonian Center for Astrophysics with participation of a large community. The HITRAN database includes spectroscopic parameters for 39 atmospheric molecules. These

Figure 1 Wavelength dependence of normalized blackbody radiation at 6000 K (Sun) and 285 K (Earth).

Figure 2 (a) Intensity of absorption of shortwave radiation by a water vapor molecule in the spectral range of $10\,000\text{ cm}^{-1}$ ($1\text{ }\mu\text{m}$) to $11\,200\text{ cm}^{-1}$ ($0.89\text{ }\mu\text{m}$). (b) Intensity of absorption of longwave radiation by a carbon dioxide molecule in the spectral range of 650 cm^{-1} ($15.38\text{ }\mu\text{m}$) to 680 cm^{-1} ($14.71\text{ }\mu\text{m}$).

include all molecule types that need to be considered for atmospheric radiative transfer, such as water vapor, carbon dioxide, ozone, methane, and other atmospheric trace gases.

The most comprehensive atmospheric radiative transfer models use the line-by-line calculations. They compute radiative transfer at individual wavelengths, and sum all wavelengths together to obtain the radiative energy. These models are computationally prohibitive to use in ocean-atmosphere models. Therefore, drastic simplifications are used to divide the entire shortwave and longwave spectra into no more than two dozen broad bands. These bands are selected based on the absorption behavior of all gas molecules in the atmosphere. Within each band, the atmospheric absorption, emission, and scattering are calculated by using various approximations. The most widely used approach is the so-called correlated- k method, in which the wavelength dependence of the absorptions is sorted according to the magnitudes (or g -points) into different bins; radiative transfer is then calculated in these bins, so that the wavelength dependence is minimized. The bins are summed to obtain the radiative fluxes in the bands; the bands are summed to obtain values for the whole spectra.

Radiative transfer calculation in the ocean is much simpler than that in the atmosphere. Radiation is absorbed in very short distances from the ocean surface. Only reflection and scattering at the ocean surface and absorption within about 30 m from the surface are calculated. The specification of the reflection and scattering contains uncertainties because the ocean surface is not perfectly flat. The atmospheric winds continuously induce waves of different scales at the surface. The absorption of radiation within the top layer of the ocean is also affected by the abundance of chlorophylls. The chlorophylls concentration is often specified from observational climatology with large uncertainties. Some ocean-atmosphere models do not include the treatment of chlorophylls in radiation calculation.

Radiative transfer in sea ice is treated the same as in the ocean but with different reflection, scattering, and absorption properties. Sophisticated models consider air bubbles and melted water that are trapped in the ice; they also consider the roughness of the ice surface. However, uncertainties of these variables are large.

Radiative transfer over land is calculated based on surface types. These include vegetation, snow, lake, bare soil, and urban structure. Vegetation is often categorized into various plant functional types. For each vegetation type, the areas and shapes of the leaves and the height of plants are assumed. For snow, the granule size, snow age, and area concentration of dark particle matters are needed as input. For bare soil, the color properties are specified as input. The radiative transfer calculation gives the amount of radiation that is reflected, scattered, and absorbed by the surface. Radiation in the vegetation influences the photosynthesis and canopy temperature, thus affecting water vapor evaporation and transpiration from the leaves. Uncertainties in the input data of radiative transfer over land can be large. The spatial heterogeneity of the input data is often difficult to parameterize.

Solar Radiation

Solar radiation reaching to the top of the atmosphere is calculated based on the Sun-Earth distance, the eccentricity (orbital shape of the Earth), the procession (the rotation of the tilted axis of the Earth), and the obliquity (the angle between the Earth's self-rotation axis and the orbital axis). Solar activities such as the 11-year solar cycle are considered in most models. The absolute amount of the output of energy from the Sun is not precise. Current satellite measurements give a range of mean incoming radiation to the top of the atmosphere, or the solar constant, from about 1370 to

Figure 3 Angular distribution of scattered radiation of an incident visible light at $0.7 \mu\text{m}$ wavelength from the left by a liquid water particle of radius (a) $1 \mu\text{m}$, (b) $10 \mu\text{m}$.

1365 W m^{-2} . Different models may use slightly different values of the solar constant.

In the transfer of solar radiation, internal emitting sources of radiation within the atmosphere can be neglected. This is a convenient simplification. However, because the wavelengths of solar radiation are prone to strong interactions with atmospheric aerosol particles and cloud particles with sizes of $1\text{--}10 \mu\text{m}$, solar radiation is strongly scattered by these particles. The scattered radiation is further scattered by the particles, leading to multiple scattering processes until they are absorbed by the particles, atmosphere, the surface, or are scattered to outer space.

Scattering of radiation by particles is highly dependent on the size of the particles and the wavelengths of the radiation as well as the electromagnetic properties of the particles. This affects the total amount of scattered and absorbed radiation, and the directional distribution of the scattered radiation. **Figure 3** shows an example of the normalized directional distribution of scattered radiation by a cloud particle in liquid phase at two wavelengths. Because of these wavelength dependences and because of the multiple scattering processes, the calculation of solar radiation involves integration across space angles. Fortunately, the multiple scattering processes smear out some of the angular inhomogeneity, so many of the bulk simplifications, such as the use of two streams to describe the directional distribution, and the averaged optical properties of the particles, can provide accurate calculation of scattered radiations.

The largest uncertainties in the calculation of the solar radiation are due to the input data, particularly cloud particles and atmospheric aerosols. Cloud processes are crudely parameterized in current ocean-atmosphere models (see later Section on **Clouds**). Atmospheric aerosols include many types; their concentration, sizes, shapes, and time evolution represent some of the largest uncertainties in radiative calculations.

Current ocean-atmosphere models all use the plane-parallel assumption in which the radiation and the atmosphere within a grid are horizontally homogeneous. Three-dimensional radiative transfer calculations have indicated that lateral radiative fluxes may reach tens of watts per square meter at the cloud scales. It is not clear whether these

lateral fluxes are important in high-resolution climate models. Three-dimensional radiative transfer calculations will incur significantly more computational costs. It is unlikely that they will be implemented in climate models in the foreseeable future.

Infrared Radiation

The surface and the atmosphere emit and absorb infrared radiation. Even though these are internal sources, calculation of infrared radiative transfer is much simpler than that of solar radiation. This is because at the wavelengths of infrared radiation, scattering by cloud particles and the majority of aerosols can be neglected.

Scattering of infrared radiation can occur on large aerosol particles. These are typically not considered in current ocean-atmosphere models. The large particles have short residence time in the atmosphere due to fast gravitational sedimentation, so the errors of neglecting them are small. Scattering of infrared radiation can also occur on cloud particles, but because absorption of infrared radiation by liquid or ice particles is large in this wavelength range, radiation is absorbed after a few scattering events, so scattering can be safely ignored.

Clouds

Clouds strongly regulate the energy balance of the atmosphere-earth system. Cloud particles reflect solar radiation to space, acting to cool the planet; they also strongly absorb infrared radiation emitted by the surface and by the below-cloud atmosphere, acting to trap infrared radiation and warm the planet. How clouds vary in response to climate changes, including variations in their area coverage, thickness, altitude, and liquid and ice water content, is the subject of intensive research in the last three decades as the cloud-climate feedback problem. Clouds are part of the hydrological cycle of the atmosphere-earth system. They are a manifestation of the phase changes of water between vapor, liquid, and ice in the atmosphere.

Cloud processes in ocean-atmosphere models are typically represented by two components. One is the cloud macrophysics; the other is cloud microphysics. The cloud macrophysical component calculates the fractional area coverage of clouds, spatial inhomogeneity of cloud properties, grid-scale condensation and evaporation, sublimation and vaporization when only a fraction of the grid domain is occupied by clouds. The macrophysical parameterization is often based on empirical relationships and assumptions on the subgrid scale distribution of total water. These empirical relationships or assumptions are approximate. They are often made differently for different types of clouds. They should be resolution dependent, but most current models are not designed to account for their dependences on resolutions.

The cloud microphysical component calculates the time evolution of the condensed cloud mass, particle number concentration, and their sources and sinks. Some cloud microphysical models only calculate the mass amount of condensed water. These models are called one-moment models. Models that include both the mass amount and number concentration are called two-moment models. To calculate the impact of aerosol on cloud microphysics, two-moment schemes are needed. Therefore, most current generation ocean-atmosphere models use two-moment schemes. Sources and sinks of cloud mass are calculated based on grid-scale condensation or sublimation, evaporation or vaporization, conversion between cloud drops and raindrops and snow, scavenging by rain and snow, breakout of raindrops or snowflakes. Sources and sinks of number concentration are calculated based on nucleation, evaporation, and vaporization of raindrops and snowflakes, and their breakup and removal by rain and snow. Figure 4 shows an example of the processes in a two-moment scheme.

Current models treat ice clouds and mixed phase clouds very crudely. Ice clouds rely heavily on the presence of ice nuclei,

whose concentration and nucleation properties are very uncertain. Ice crystals form in different shapes as functions of the ambient air conditions and ice nuclei. Different shapes have different density and falling speed. The most common practice in current models is to use a ramp function of temperature to calculate whether the clouds are liquid, ice, or mixed phase.

Precipitation

Precipitation processes include the formation and changes of raindrops, snowflakes, and their evolution in the falling process to the ground. Some models also include categories of graupels and hails. Similar to cloud microphysical models, if a model only calculates the precipitation mass, it is called a one-moment scheme; if a model calculates both the mass and number concentration of precipitation particles, it is called a two-moment scheme. The separation of cloud particles and precipitation particles is based on observational support that the size distributions of these two types of particles are typically well separated, and so they have very different falling speeds.

Formation of precipitation is calculated from conversion of cloud drops and ice crystals, and collection of cloud particles by the larger falling precipitation particles. The conversion occurs because cloud particles have different sizes and different sedimentation velocities. Large particles fall faster than smaller particles, and so the small particles are captured by large particles. Since the size distribution of cloud particles in current models is approximate, the formulation of the cloud-to-precipitation conversion contains many empirical parameters.

One efficient mechanism for precipitation particles to grow occurs in mixed phase clouds. The saturation vapor pressure over water is greater than over ice. In mixed phase clouds, water vapor is saturated with respect to liquid droplets, but super-saturated over ice particles. As a result, liquid particles can

Figure 4 Schematics of some of the cloud and precipitation microphysical processes.

rapidly evaporate to sublimate to the ice particles to make them grow. This process, also called Bergeron process, is calculated in the precipitation parameterization. It also applies to ice crystals falling into supercooled liquid clouds.

Besides their formation, precipitation particles evolve along their falling path before reaching the ground. They accumulate cloud particles or smaller precipitation particles; they also experience evaporation or vaporization and breakup. The accumulation depends on the falling speed of the precipitation particles, which require information of their sizes and shapes. For raindrops, spherical shape can be safely assumed, but for snowflakes, since their shapes are highly uncertain and are crudely parameterized, the falling speed is approximate. The evaporation and vaporization of falling precipitation particles depend on the relative humidity of the ambient air, often taken as the mean condition of the grid domain, which may not be accurate.

Turbulent Mixing

Turbulent transports or mixing of heat, momentum, and constituents refer to the effects of subgrid scale processes on the resolved-scale fields. Because these subgrid scale processes operate at all scales smaller than resolved-scale fields, even in high-resolution models with grid spacing of several kilometers, turbulent transports still need to be parameterized. Turbulent fluxes are an essential part of any ocean-atmosphere model. For example, the turbulent transport of water vapor from the surface to the atmosphere is equal to the global precipitation.

Equations of turbulent fluxes can be formulated if higher order subgrid transport terms are known. The calculation of these high-order terms requires even higher order terms. The equations are therefore not closed and approximations are made to parameterize some terms. The simplest type of turbulence parameterization is a diffusion scheme, in which the turbulent flux is represented by the vertical gradient of a field multiplied by a diagnostically calculated diffusivity. These schemes are called first order model. The diffusivity is typically a specified function of vertical static stability and wind shear, or the dimensionless Richardson number. In some models it is calculated as a prescribed function of height, with a peak in the middle of the boundary layer to mimic results from large-eddy simulation models. Some models also add a counter-gradient term to the down-gradient diffusion term to account for large-eddy transport. This term is parameterized based on the source of large eddies such as surface buoyancy fluxes.

Some models prognostically calculate the turbulent kinetic energy (TKE) based on buoyancy flux, shear production, transport, and dissipation of eddy energy. This energy is then used in the calculation of the diffusivity. Other models may diagnostically calculate TKE. If the TKE is diagnostically calculated, the scheme is still first order; if it is prognostically calculated, the scheme is often called one-and-half order, since not all of second order moments are prognostically calculated. Very few models use second order or higher order closure schemes.

In the atmosphere, two separate types of turbulent transports are typically parameterized. One is for the free

atmosphere that is away from the atmospheric boundary layer (ABL); the other is for the ABL. There are no fundamental differences in the philosophy of their parameterizations, except for the degree of simplifications. In the ABL, most models first judge whether the layer is a stable boundary layer or unstable boundary layer. Different closure assumptions are used based on the stability. Convective boundary layer, in which the surface upward buoyancy flux is positive, is the most common type ABL.

In the ocean, the boundary layer turbulence is driven by wind mixing, shear of ocean currents, and static instability. The static instability can be caused by cooling of ocean surface and salinity change. The parameterization of oceanic turbulent fluxes in the vertical direction uses similar approaches as that for the atmosphere. In the horizontal direction, however, turbulent mixing in the ocean has two more complications than that in the atmosphere. First, because of the long timescale of ocean circulations and the large role of mesoscale eddies, horizontal turbulent mixing cannot be neglected. Earlier models parameterize the horizontal diffusivities of small and mesoscale eddies on the native model horizontal surfaces. Current generation models formulate them along the isopycnal or density surfaces. A second complication is the turbulent mixing along the lateral boundaries. The same equations as for the vertical boundary layer are often used, in which the turbulence is primarily driven by horizontal shear of ocean currents.

Surface Fluxes

Surface fluxes include shortwave and longwave radiative fluxes, and the heat, momentum, constituent fluxes across the interfaces between the atmosphere and the ocean or land. The radiative fluxes are calculated from the radiative transfer parameterizations described in previous sections. The turbulent heat, momentum, and constituent fluxes across the surface are calculated using similarity theory instead of the eddy diffusivities because the turbulence at the surface is strongly confined by the surface geometry.

In the similarity theory, a length scale – the Monin-Obukhov length scale – is used to normalize the height in the surface boundary layer. Empirical relationships of the vertical profiles of the winds, temperature, and constituents are obtained with respect to this normalized height based on observations. The surface fluxes appear as constant parameters in the profile relationships and in the Monin-Obukhov length scale. Vertical integration of these profiles from the surface to a reference height gives the formula to calculate the surface fluxes. The most widely known forms are

$$\tau = -\rho_{\text{air}} C_D |V_{10}| v_{10}$$

$$H = \rho_{\text{air}} C_H |V_{10}| (T_s - T_2)$$

$$E = \rho_{\text{air}} C_E |V_{10}| (q_s - q_2)$$

where τ , H , E are surface momentum stress acting on the atmosphere, surface heat flux, and constituent (such as water vapor) fluxes respectively; ρ_{air} is the density of air; V_{10} is the

wind at 10 m height; T_s , q_s are temperature and the constituent concentrations at the surface; T_2 , q_2 are temperature and constituent concentrations at 2 m; C_D , C_H , C_E are the bulk transfer coefficients of momentum, heat, and constituents. These coefficients are dependent on the fluxes themselves, so iterations are needed. In simple calculations or applications, however, they are often specified as constants.

At the ocean–atmosphere interface, net flux of freshwater is needed to calculate the salinity. The freshwater flux to the ocean is calculated by simply taking the difference of precipitation and surface evaporation.

Convection in the Atmosphere and Oceans

Convection is one type of turbulence, but because it is highly anisotropic in the vertical and horizontal directions, it is always separately parameterized. Convection schemes are used to calculate the convective transport of heat, momentum, constituents, and their sources and sinks within the convective portion of a grid cell.

Most atmospheric convection schemes use mass-flux plume models. These schemes parameterize the triggering condition of convection that determines when and where convection is activated. They also parameterize the entrainment and detrainment rates of the plume mass, the vertical distribution of the convective mass fluxes, and the cloud microphysical processes within the convective plumes.

The triggering condition of convection always includes atmospheric conditional instability as one criterion. However, models differ in using additional factors, such as the origination level of convection, whether the instability is calculated for undiluted or diluted air parcels, whether convection can be inhibited by a layer of negative buoyancy, and whether resolved-scale dynamics are considered. Lateral entrainment and detrainments can also differ greatly among different models: some use specified rates; others calculate them as functions of humidity of the ambient air; some even ignore them altogether. Convection mass fluxes are often calculated using closure assumptions, which are subject to considerable uncertainties. Cloud microphysical processes within convection are typically crudely parameterized such that when the condensed water exceeds a threshold value, the excess amount is treated as precipitation. These assumptions represent some of the largest uncertainties in current ocean–atmosphere models.

Most current convective parameterizations are diagnostic. They are not passed from one time step to another time step. Almost all schemes are designed for models with grid sizes that encompass an ensemble of cumulus clouds. As high-resolution models become more popular, these convection schemes may need structural improvements to correctly reflect their temporal and spatial effects on resolved-scale motions.

Atmospheric convective parameterizations often include separate schemes for shallow convection and for deep convection. The essential elements of these two types of schemes are the same. The differences are due to the different depth of the instability layer so that different assumptions are used for the entrainment and detrainment rates. In addition,

because deep convection is typically thicker and is with larger instability, it is associated with strong precipitation, whose evaporation causes downdrafts.

Convection parameterization in the ocean typically uses simple adjustment schemes. Vertically unstable water column is adjusted to neutral stratifications. Convection is often initiated because of density anomaly at the ocean surface, which can be caused by radiative or evaporative cooling.

Gravity Waves

Most models parameterize the effects of internal gravity waves on the resolved-scale flow. These waves cannot be resolved by the large-scale models because of their small vertical and horizontal wavelengths. These gravity waves are calculated by using information of terrain, jets, or frontogenesis in highly idealized forms. The calculation also considers saturation of gravity waves for which the vertical wavelength is small enough to cause static instability. Momentum transport by the gravity waves is then obtained and vertically differentiated to obtain the momentum wave drag.

It has been shown that the momentum wave drag has a large impact on the mean zonal wind of the stratosphere and the temperature in polar regions. Large gravity wave drag slows down the westerly jet in the stratosphere and warms the polar stratosphere. Gravity wave parameterizations often contain many empirical parameters that are subject to large uncertainties.

Aerosols

Modern ocean–atmosphere models all include aerosols as prognostic variables. Aerosols not only affect radiation directly but also impact the cloud condensation nuclei and therefore clouds. These two effects are called aerosol direct and indirect effects on climate. The role of anthropogenic aerosols – aerosols caused by human activities – in past and future climate change has been a subject of intensive research in the last two decades.

Aerosols in the models are typically categorized into groups. These often include sulfate, ammonia, sea salt, dust, black carbon, and organic carbon. The mass amount and number concentration of each group are calculated. Assumptions are made on the size distributions of aerosols and how they are mixed, since these determine the radiative properties, water activity, and chemical reactions of the aerosols.

The parameterizations of aerosols include emissions of both natural and anthropogenic sources, such as dust and sea salt from natural emissions, sulfate and ammonia from anthropogenic sources. Aerosols are also calculated to evolve with time according to gas-particle conversion, coagulation, and chemical aging in addition to transport. The gas-particle conversion involves many types of precursor gases that originated from organic sources, many of which are not well known. Sinks of aerosols are removals by dry and wet depositions.

Superparameterizations

Superparameterization refers to the use of cloud-resolving models as a substitute of some physical parameterization components (cloud macrophysical and convection schemes) in large-scale atmospheric models. Since cloud-scale dynamics are resolved and the clouds are calculated based on these resolved-scale fields, superparameterization is superior to traditional parameterizations of cumulus convection and cloud processes. The disadvantage is the more expensive computational cost.

Current superparameterizations use spatial grid sizes of about 1 km in the cloud-resolving models. Boundary-layer turbulences and cloud microphysics still rely on parameterizations. Superparameterizations have been only recently used in coupled ocean-atmosphere models for limited amount of simulations.

Performances of Ocean-Atmosphere Models

When forced with incoming solar radiation, current ocean-atmosphere models are able to simulate earthlike global distribution of surface temperature, vertical distribution of atmospheric winds and ocean currents. They can also simulate cyclones, storm tracks, stationary waves, and interannual variability of tropical ocean temperature that resembles the observed El Niño events. As two examples, Figure 5 shows the simulated annually averaged global distribution of sea-surface temperature by the Community Earth System Model Version 1

and its comparison with observation. Figure 6 shows the simulated atmospheric zonally averaged eastward winds in the December–February months and its comparison with observation. The model is able to reproduce most of the important observational features in the ocean surface temperature and in the atmospheric winds.

Ocean-atmosphere models have been also used to simulate past climate change and to make projections of future climate. To calculate past changes, the models are given time-dependent forcing fields of greenhouse gases such as CO₂, solar variability, volcanic forcing, anthropogenic aerosol changes, and land use and land cover changes. Most models are able to simulate the global temperature increase in the twentieth century. These results have been summarized in the past reports of the Intergovernmental Panel on Climate Change.

Common Biases

There are several common biases in virtually all coupled ocean-atmosphere models that researchers have been trying to solve in the last several decades. One is the so-called double ITCZ syndrome. It refers to a double intertropical convergence zone (ITCZ) simulated by the models in the annual mean precipitation in the central Pacific that is not present in observations (Figure 7). Higher spatial resolutions do not seem to improve this aspect of the model simulations. The second long-standing problem is the overall failure of most models in simulating the Madden-Julian oscillation, which is an

Figure 5 Annual mean sea surface temperature: (a) simulation by the Community Earth System Model Version 1; (b) observation. ANN refers to annual averages.

Figure 6 Height–latitude cross-section of eastward atmospheric wind averaged over all longitudes: (a) simulation by the Community Earth System Model Version 1; (b) observational estimates. DJF refers to December–January–February season. ECMWF refers to observational reanalysis at the European Center for Medium Range Weather Forecasting.

Figure 7 Annual mean precipitation: (a) simulation by the Community Earth System Model Version 1; (b) observation from the Global Precipitation Climatology Project (GPCP).

intraseasonal propagation of atmospheric circulation anomalies and convection from the equatorial eastern Indian Ocean to the western Pacific with a period of about 30–60 days. This intraseasonal oscillation has been shown to affect weather in many regions of the globe. The third common bias is the misrepresentation of the diurnal variation of precipitation over

the oceans. Models simulate peak precipitation at noontime, but observations show peak precipitation during the night over most regions of the oceans. All these biases are believed to be due to inaccurate physical parameterizations in the models.

Individual models may have other significant biases, including the simulations of El Niño and its impact, monsoon

rainfall, the deep ocean circulation, and land surface temperature. All these biases are being actively studied in the modeling centers.

Synopsis

General circulation models (GCMs) are essential tools for climate studies. The history of the general circulation modeling is broadly divided into three phases characterized, respectively, by the rapid development of theories on large-scale atmospheric motion, development of early GCMs, and expansion of internal processes and use of higher resolutions. The scope of general circulation modeling is outlined. The basic approximations, boundary conditions, discretization of the governing equations, and the problem of parameterization of physical processes are addressed. Current trends toward unification and the reduction of the dependency of model physics on grid size are mentioned.

Introduction

General circulation of the atmosphere refers to the time-averaged, planetary scale motion representing the atmosphere's long-term statistical behavior. General circulation models (GCMs) numerically integrate the equations of fluid motion to simulate the evolution, maintenance, and variations of the general circulation. GCM applications, for example, climate simulations or predictions of the second kind, do not generally emphasize the dependence of the solution on initial conditions. A comprehensive GCM can also be used as an extended numerical weather prediction (NWP) model. In NWP applications, or climate predictions of the first kind, initial conditions are crucially important.

The History of General Circulation Modeling

The start of general circulation modeling is hardly distinguishable from that of NWP. V. Bjerknes first advocated the idea of NWP in the early twentieth century. L.F. Richardson carried out a pioneering albeit unsuccessful NWP attempt in 1922. The history of general circulation modeling that would follow can be divided into a prelude and three phases (I, II, and

III, see Figure 1). The prelude was characterized by the rapid development of quasigeostrophic theories on large-scale atmospheric motions in the late 1940s.

Phase I began in 1950 when Charney, Fjörtoft, and von Neumann obtained successful 24-h forecasts of 500 hPa geopotential height using the two-dimensional quasigeostrophic vorticity equation. This success demonstrated the relevance of a simple dynamical model for daily weather changes, and dynamic meteorology and synoptic meteorology began to merge. Another epoch-making event during Phase I was the recognition that the dynamics of 'cyclones' and that of the 'general circulation' were closely linked. The numerical experiment performed by Philips in 1956 using a quasigeostrophic two-level model with prescribed heating highlighted those links. In the experiment, the large-scale components of initially random disturbances grew due to baroclinic instability, modifying the general circulation from the zonally symmetric regime to the wave regime. Correspondingly, the zonally averaged meridional circulation in the middle latitudes changed from the Hadley type to the Ferrel type, producing midlatitude surface westerlies. Philips's 1956 experiment, therefore, captured fundamental features of the observed general circulation of the atmosphere, whose causes had been more or less a matter of speculation.

Figure 1 A chart showing the history (and near future) of numerical modeling of the atmosphere.

The beginning of Phase II of general circulation modeling roughly corresponds to the development of early GCMs, including those at the Geophysical Fluid Dynamics Laboratory (GFDL), University of California, Los Angeles (UCLA), Lawrence Livermore National Laboratory (LLNL), and National Center for Atmospheric Research (NCAR). Major changes from Phase I to Phase II are listed below:

- The use of the primitive equations (i.e., the governing equations without quasigeostrophic or similar approximations on the balance between the mass and velocity fields) became standard;
- Computational difficulties associated with the use of the primitive equations and their long-term integration were essentially overcome;
- Heating was made the result of motion, as well as the cause of motion, including water-vapor mixing ratio as a standard prognostic variable; and
- The importance of parameterized representation of subgrid processes, cumulus parameterization in particular, was clearly recognized.

Development of these early GCMs stimulated the meteorological community to look into the feasibility of a global observation and analysis experiment. The Global Atmospheric Research Program (GARP) then followed at an unprecedented scale in the atmospheric sciences. GARP tremendously stimulated and supported worldwide efforts in general circulation modeling almost throughout Phase II. During this phase, the scope and diversity of numerical modeling of the atmosphere models, including the development of oceanic GCMs and atmospheric models, focused on smaller domains/scales as shown in Figure 1.

The history of general circulation modeling is now in Phase III (see Figure 1). The beginning of this phase is marked by the development of coupled atmospheric and oceanic GCMs. More details on developments during Phase III are presented after a general discussion on the scope of general circulation modeling.

The Scope of General Circulation Modeling

The principal energy source for the general circulation is solar radiation, which influences the atmosphere rather remotely. The various heat components in the atmosphere (and in the climate system) are produced by complex interactions among the processes shown in Figure 2. (Here Large-Scale means scales larger than convection and turbulence scales, and Dynamical Processes includes associated adiabatic thermodynamical processes.) The horizontal scales of different atmospheric phenomena are shown in Figure 3. (Here the arrow indicates the smallest scale explicitly resolved by typical contemporary GCMs.) Although there is a trend to use higher resolutions as computer technology advances (dashed arrow in Figure 3), the collective effects of unresolved processes cannot be ignored and, therefore, they must be formulated in terms of the resolvable-scale prognostic variables unless the resolution is sufficiently high to explicitly simulate individual clouds. This is the 'parameterization problem,' which represents a crucial part of general circulation modeling.

Figure 2 Basic processes in the climate system and their interactions.

Basic Approximations and Upper and Lower Boundary Conditions

Most GCMs use the 'quasistatic approximation,' in which the hydrostatic equation replaces the vertical component of the momentum equation and Coriolis and metric forces that depend on the vertical velocity are neglected in the horizontal component of that equation. The approximation eliminates vertically propagating sound waves, and is justifiable when motions have a sufficiently large horizontal scale (say, $\gg 15$ km with typical static stability). In the 'primitive equations,' the quasistatic approximation is the only major simplification on dynamics.

When the model top corresponds to the top of the atmosphere, it is reasonable to assume that there is no vertical mass flux across the upper boundary. This condition can be artificial, however, even when the upper boundary is formally placed at the top of the atmosphere, because of practical limitations on vertical resolution. At present, no simple but fully justifiable way of handling the upper boundary is available for general use in nonlinear discrete models.

For a horizontally discrete model, the effective height of the surface at the model's lower boundary may be higher than the actual height averaged over the grid box. The additional height depends on the subgrid-scale variance of orographic height. Considerations of this sort lead to the idea of 'envelope orography.' Most GCM applications during Phase II prescribed the geographical distribution of sea surface temperature (SST).

Discretization of the Governing Equations

In numerical modeling, the governing partial differential equations are replaced by a finite number of algebraic equations. Such a 'discretization' may seriously distort certain dynamical aspects of the continuous system even when a reasonably high resolution is used. The appropriate handling of this aspect is particularly important in GCM applications that require long-term integrations.

Figure 3 Horizontal scales of typical atmospheric motions.

Basic Terminology

When the Eulerian expression of the material time derivative ($D/Dt = \partial/\partial t + \mathbf{V} \cdot \nabla$) is used, discretization is made in space and time. Space discretization can be done using either *finite-difference/finite-volume methods* or *spectral methods*. In the former (or grid point) methods, differential operators in the equations are replaced by difference operators both in the horizontal and in the vertical. In spectral methods, the dependent variable is replaced by a function expressed in the horizontal as a *finite* series with global basis functions. Spectral methods are usually combined with the *transform method*, in which products in nonlinear terms are calculated at grid points in the physical space rather than as interactions of waves.

If variables at a new time level appear not only in the finite-differenced time derivatives, the scheme is *implicit*; otherwise it is *explicit*. *Semi-implicit* schemes, in which implicit expressions are used in selected terms in the prognostic equations, such as the pressure gradient force in the horizontal momentum equation, are often used to allow for longer time intervals while maintaining computational stability. A semi-implicit scheme is almost always used in the spectral method.

The *semi-Lagrangian* method is becoming increasingly popular for the advection (or the advection part of) equation. Removing the restriction on the time interval due to the Courant–Friedrichs–Lewy (CFL) condition is the major motivation for the Lagrangian approach. Semi-Lagrangian schemes consider trajectories whose arrival points coincide with grid points, which are fixed in space, while values at departure points are determined by interpolations from grid points. These schemes are generally combined with the semi-implicit method.

Vertical Coordinates and Grids

The choice of vertical coordinate can make substantial differences in a discrete system. Most existing GCMs use the σ coordinate (σ is the pressure divided by surface pressure and hence

at the lower boundary $\sigma = 1$) or a hybrid σ – p coordinate, where p is the pressure. The lower boundary condition is simple with a coordinate of this type. The pressure gradient force, however, consists of the sum of two terms with comparable magnitude and opposite sign over steep topography. Discretization errors, therefore, can be serious in the sum even when they are small in individual terms.

The most commonly used vertical grid for primitive equation models is the Lorenz grid, shown in [Figure 4\(a\)](#) for the σ coordinate. With this grid, the model atmosphere is divided into sublayers, and the ‘vertical velocity’ of the coordinate ($\dot{\sigma} \equiv D\sigma/Dt$) is defined at the interfaces between the sublayers. The budget equations for mass and three-dimensional prognostic variables, such as horizontal velocity v and potential temperature θ , are then applied to the sublayers. The Lorenz grid, therefore, is convenient for keeping track of budgets of three-dimensional variables. There is, however, a computational mode in the vertical structure of θ . This problem does not exist in the Charney–Phillips grid shown in [Figure 4\(b\)](#), which predicts θ at the interfaces where $\dot{\sigma}$ is defined.

Most GCMs use a Eulerian finite-difference system in the vertical. The number of vertical levels in current GCMs varies roughly between 30 and 60, and even higher.

Horizontal Coordinates and Grids

Most GCMs use longitude–latitude grids based on the spherical coordinates. Finite-difference methods based on such grids, however, must deal with the ‘pole problem’ as meridians converge near the poles. There are solutions to this problem but none is fully satisfactory. Spectral methods based on spherical harmonics avoid the problem, but have difficulties in advecting highly variable positive definite scalars such as moisture. When the quasiuniform spherical ‘geodesic’ grids generated from icosahedra or other Platonic solids are used, the pole problem does not exist.

Conceptually, the simulation of large-scale atmospheric flow requires the proper simulation of geostrophic adjustment

Figure 4 The Lorenz and Charney–Phillips vertical grids with the σ coordinate.

by dispersion of inertia–gravity waves and that of the slowly changing flow after geostrophic adjustment has taken place. The simulation of geostrophic adjustment can be greatly affected by the choice of horizontal grid structure through different dispersion properties of the inertia–gravity waves in the discrete system. Figure 5 shows some grid structures for the shallow water equations, where h is the free surface height, and u and v are the horizontal velocity components. The nomenclature Grid A through Grid E with h replaced by a scalar prognostic variable is often used for describing the horizontal grid structure of GCMs. The computational design for slowly changing flow is also important in making long-term integrations of the governing equations. Here, avoiding excessive nonphysical production or dissipation of quadratic functions of prognostic variables has been found to be effective.

The horizontal resolutions of current GCMs vary widely according to the intended applications. Grid sizes used for

low-resolution climate simulations are around 200 km, while for NWP the grid size can be about one order of magnitude smaller.

Parameterization of Physical Processes

GCMs include formulations of most or all of the physical processes shown in Figure 2. Those formulations critically affect the quality of the GCM simulations.

Radiation

The net radiative heating is obtained from parameterizations of radiative transfer by visible and near-infrared solar radiation and cooling by longwave terrestrial radiation. The calculations are usually made for clear and cloudy conditions.

Figure 5 Distributions of the dependent variables on horizontal grids A through E.

For the solar radiation, computing absorption requires consideration of all absorption lines of atmospheric constituents at each grid point. Since this is too demanding, methods used are based on functional relations for absorption in fairly broad spectral intervals. Scattering of solar radiation must be considered. One approach to include scattering is to assume that the radiation can be divided into upward and downward streams of radiant energy ('two-stream' methods). For the longwave radiation, the principal gases considered are H_2O and CO_2 . Other important gases are O_3 , CH_4 , N_2O , and CFCs. The calculation is also performed by band models.

Radiative calculations require specification of part of the grid box covered by clouds (fractional cloud cover). There are different approaches to the formulation of fractional cloud cover, which remains one of the major uncertainties in current GCMs.

Formulation of Planetary Boundary Layer (PBL) Processes

The standard practice in numerical models of the atmosphere is to calculate surface fluxes using the bulk aerodynamical method. The Monin–Obukov surface layer similarity theory shows that the transfer coefficients depend on the surface roughness length and the bulk surface Richardson number.

In view of the vertical resolutions in GCMs, however, values in the surface layer are unknown and must be diagnosed from the values predicted above. One of the main differences between PBL parameterizations for GCMs is in the representation of PBL processes above the surface layer. Recently, the importance of representing (vertically) nonlocal effects of PBL turbulence has been widely recognized. Processes crucial for a cloud-topped PBL, however, are included only in a few GCMs.

Dry Convective Adjustment

If the temperature lapse rate exceeds the dry adiabatic lapse ($\partial\theta/\partial z$ is negative), the atmosphere is dry convectively unstable and small-scale (dry) convection will develop. In most GCMs, this process is parameterized as an instantaneous adjustment of the unstable vertical profile of θ to a neutral profile.

Condensation Processes

Most GCMs include grid-scale condensation as adjustment to a saturated state when the water–vapor mixing ratio at a grid point tends to become supersaturated.

If the temperature lapse rate exceeds the moist adiabatic lapse rate and if the relative humidity is sufficiently high, small-scale cumulus convection is expected to develop. Formulating the collective effects of such cumulus convection, which is not resolved by usual GCMs grids, in terms of resolvable-scale prognostic variables is called *cumulus parameterization*.

There are schemes in which cumulus effects are directly formulated using large-scale low-level convergence as the forcing mechanism. An increasing number of cumulus parameterizations currently used, however, formulates the effect of moist convective processes on large-scale fields as cumulus adjustment and correspondingly identify, if necessary, how large-scale processes control cumulus convection against the adjustment (large-scale forcing). This is typically done as a combination of a one-dimensional cloud ensemble model and an assumption on the quasiequilibrium states. These states can be considered as neutral or marginally unstable states from the viewpoint of moist convective instability.

There are still a number of uncertainties in formulating cloud processes for a cumulus parameterization, as illustrated by the question marks in Figure 6. During the last decade, there has been a new development, called *superparameterization* or *multiscale modeling framework (MMF)*. In this approach, cumulus parameterization is replaced with simulation of cumulus convective processes by two-dimensional cloud-resolving models (CRMs) embedded within each grid cell of the GCM. In this way, most of the cloud-scale interactions shown in Figure 2 are considered.

Parameterization of Cloud Fields

The coupling between radiative and dynamical–hydrological processes through time-dependent cloudiness has been either completely neglected or modeled very crudely even in comprehensive GCMs. This represents the major uncertainty on the role of cloud feedbacks in climate change.

Figure 6 Outstanding questions in modeling cloud processes for cumulus parameterization.

The standard method for determining time-dependent fractional cloudiness is based on an empirical diagnostic relationship between its values and relative humidity. Even when this approach is applicable, however, prediction of mean relative humidity cannot be done without considering subgrid-scale cloud processes. A more physical determination of cloud effects on radiation involves the following problems:

1. Determination of the total amount of cloud water–ice in a grid box;
2. Determination of cloud geometry including the variation of cloud water–ice within a grid box; and
3. Determination of the radiation properties of clouds.

An increasing number of GCMs uses a ‘partially prognostic’ approach for 1, in which mean cloud water–ice mixing ratio is predicted with an advection inclusion with parameterized microphysics. A ‘fully prognostic’ scheme, which predicts cloudiness through explicitly including cloud generation processes involving 1–3 has begun to be used in some GCMs.

Subgrid-Scale Orographic Gravity Waves

Internal gravity waves forced by subgrid-scale orography can produce a drag at the surface. Near the surface, however, the deceleration effect due to this drag is compensated by convergence of the downward momentum transport by the waves. Thus the actual deceleration can happen remotely at higher levels where wave breaking takes place. Most current GCMs include a parameterization of this effect due to subgrid-scale orographic gravity waves.

Land Surface Processes

In the simplest (and earliest) approaches to represent land surface processes in GCMs moisture conditions are prescribed at the lower boundary. This may produce reasonable mean evaporation fields, but it precludes land–atmosphere interactions. The simplest interactive approach is the so-called bucket model, in which water level in a reservoir of soil moisture increases due to precipitation and decreases due to evaporation (and runoff).

More recent approaches give vegetation a more direct role in determining the surface energy and water balance, particularly by allowing stomatal conductance (and thus evaporation efficiency) to decrease in response to increased environmental stress. Recent trends include the explicit representation of spatial heterogeneity in surface characteristics within a surface element.

Microphysical Processes

Many GCMs have recently incorporated parameterized microphysical processes. These include condensational growth of cloud droplets, depositional growth of ice crystal, homogeneous, heterogeneous, and contact freezing of cloud droplets, and autoconversion of cloud droplets. They also include aggregation of ice crystals, depletion of cloud ice and cloud droplets by snow and of cloud droplets by rain, evaporation of cloud water and rain, sublimation of cloud ice and snow, and melting of cloud ice and snow.

Chemical and Aerosol Processes

Early attempts to combine GCMs and chemistry models followed an ‘off-line’ approach, in which fields generated by the former (e.g., winds) drive the latter (e.g., chemical species). More recently, GCMs and chemistry models have often been coupled ‘online,’ thus allowing for the feedbacks among dynamical, radiative, and chemical processes. In some cases, the chemistry models also calculate the advective and convective processes that transport chemical species; in others these processes are calculated by the GCM itself.

Water Isotopes

Water isotope diagnosis has been incorporated into some GCMs. Isotopes are influenced by many factors such as precipitation amount, regional geography, and distance from the sources of precipitating water. Additional difficulties for interpretation of results in terms of paleoclimate are that isotope–temperature relationships seem to vary with climate state.

GCM Applications

GCMs have two primary applications: (1) weather and climate prediction, and (2) investigations aimed to increase the understanding of the climate system and its variability. For deterministic NWP the model is initialized by combining model predicted and observed data. The current standard technique for prediction is based on performing multiple runs from slightly different initial conditions (‘ensemble integrations,’) in which each ensemble may have a few dozen members. At present, the limit of practical predictability achieved by deterministic forecasts is 7–8 days in winter, as determined by midlatitude anomaly correlation 60% score. GCMs coupled to an oceanic GCM are used for climate predictions of the first kind. It is too early to determine the limit of practical predictability in this case, but successes from several months in advance have been documented.

For the second application, the typical methodology for research starts by performing a GCM simulation long enough to achieve quasiequilibrium, which is then defined as the model’s climate. The next step repeats the simulation by altering the model component representative of the process under investigation. One of the earliest applications of this technique addressed the role played by the Himalayas on the Indian summer monsoon by comparing model climates with and without those elevations. The technique has been applied extensively to examine the global impacts on the atmosphere of SST anomalies, such as those associated with El Niño and La Niña events in the Pacific Ocean as well as similar features in the other oceans. Another application is the impact on climate of variations in surface conditions as consequence of climate change (see [Figure 7](#)). The underlying assumption in all these experiments is that one can separate the anomalies in climate from those that are ultimately associated with variations in boundary conditions.

Another important GCM application has been climate change expected as a result of the changing atmospheric composition. GCMs are particularly suitable for this problem, which involves many interactions and feedbacks. The impact of

Figure 7 Ocean temperature anomalies (K) at 160-m deep simulated by the UCLA coupled atmosphere–ocean GCM as the response to melting of the Greenland ice sheet. Values correspond to the average between years 26 and 30 after the melting started. Courtesy of N. Argawal, MPI.

increased greenhouse gases has been assessed by comparing model climates with different concentrations of those gases. For these studies, atmospheric GCMs (AGCMs) have been coupled to ocean models of diverse complexity. This has allowed for exploring how the oceans can delay the effects of a greenhouse warming. More recently, the role of increasing sulfate aerosols has been questioned and GCMs have been coupled to sulfur chemistry models. This has allowed for an assessment of the indirect aerosol forcing problem, namely the impact on climate of changes in reflectivity, formation, and residence time of clouds in the presence of aerosols.

GCM simulations with prescribed concentrations of ozone in the lower stratosphere from observational data suggest that depletion of lower stratospheric ozone is the major radiative factor in accounting for the 1979–90 cooling trend in the global, annual-mean stratosphere, with a substantially lesser contribution by the greenhouse gases. Other studies have addressed the interactive radiative–chemistry–dynamical effects of ozone losses in the Antarctic polar region during the southern spring.

Computational Aspects

The computer code of all contemporary GCMs is highly optimized for vector computer architectures. Most models have also been ported to massively parallel computer architectures. AGCM codes are very heterogeneous and their optimization is not simple. The major current parameterizations operate in vertical columns of the atmosphere. If a two-dimensional grid partition

in the horizontal (longitude–latitude) is used, very little communication is required between processors for that part of the code. However, the amount of calculations (e.g., those for moist convection) can strongly vary in space and time resulting in a dynamic load imbalance. The ‘pole problem’ requires application of Fourier filters, resulting in a static load imbalance. Performances in the order of 400 Gflops have been reported.

GCM Verification

Verification of GCM performance is a challenging problem. In NWP, a standard value of performance is given by the correlation between predicted and observed fields to which the long-term model and observed climatology have been subtracted, respectively. It is currently accepted that values larger than 0.6 of such an ‘anomaly correlation’ computed by using the geopotential height field at 500 hPa correspond to ‘useful’ results. For climate simulations, early validations compared monthly means of simulated and observational fields, with emphasis on quasistationary planetary waves, eddy statistics, and monsoon circulations. Early in the 1990s, a number of AGCMs participated in a coordinated effort on verification of their performance. This was based on the comparison between outputs from simulations with the same prescribed boundary conditions corresponding to the period 1979–88. This coordinated approach has been extended to coupled atmosphere–ocean–land models in simulations that can extend up to centuries. Several efforts are also underway on the development of quantitative metrics for the success of climate simulations.

Single-column models (SCMs) have been used to test selected physical parameterizations. An SCM consists of an isolated, time-dependent GCM column forced and constrained with observational estimates of advective fluxes, and whose outputs are compared with observational data generally provided by field programs.

Current Directions

From the point of view of climate simulations, prescribing SST as in most applications during Phase II assumed the most important part of the answer and, therefore, it might have hidden crucial deficiencies of GCMs. The coupling of an AGCM with an oceanic GCM to predict SST at the beginning of Phase III started a trend toward expansion of internal processes. While there is no question about the merits of such expansion, it also demands a higher level of modeling effort. The elimination of prescribed external conditions, such as SST, uncovered model deficiencies that are serious even for simulating the present climatology. For example, most contemporary coupled atmospheric–oceanic GCMs tend to produce a climate that is significantly more symmetric about the equator than in both the atmospheric component with prescribed SSTs and the observation. Inclusion of land surface models in AGCMs revealed similar difficulties. Inclusion of other modules such as sea ice has motivated the nomenclature ‘Earth System Models.’

Another outstanding trend in Phase III is the use of higher resolutions as computer technology advances, resulting in model resolution increases. This makes the separation more ambiguous between resolvable processes, which can be highly transient, and parameterized unresolvable processes, which can only be near a statistical equilibrium. Various processes shown in [Figure 2](#) interact too strongly to be separately formulated, especially when clouds are involved. A key goal of Phase III will be a unification of those formulations and the reduction of

the dependency of model physics on grid size, which is an artificial length introduced for computational purposes. To achieve the goal, a trend to use the nonhydrostatic dynamics core and explicit simulation of cloud-scale motions even for simulating the global climate has already begun. This includes the global cloud-resolving models (GCRMs) and global models with ‘superparameterization’ or ‘MMF,’ in which the conventional cumulus parameterization is replaced by explicit simulations of convective processes using CRMs with a limited spatial dimension. The MMF has already been used for a variety of climate studies with encouraging results. Attempts to broaden the applicability of MMF with the goal to unify MMF and GCRM are also being made.

Synopsis

Numerical modeling of the atmosphere is challenging because of the enormous range of space and timescales involved, and because many qualitative features, such as balance and conservation, must be accurately captured. We discuss here a number of topics that have proved important historically in the development of numerical models of the atmosphere, including spatial discretization and its relation to representation of model fields, choice of vertical and horizontal grids, time integration schemes, advection schemes, and solution methods for elliptic problems.

Special Challenges in Numerical Modeling of the Atmosphere

The atmosphere has a number of characteristics that make numerical solution of its governing equations especially challenging. Most obvious is the geometry. The atmosphere is highly anisotropic, with vertical length scales being typically much smaller than horizontal. Gravity acts in the vertical direction, and the atmosphere is strongly stratified and close to hydrostatic balance. The ratio of horizontal to vertical model resolution is commonly chosen to capture this anisotropy, and model grids and methods must be able to represent hydrostatic balance (see Section on [Grids](#) below). For global modeling, the grid and methods chosen must be able to represent the (approximately) spherical geometry of the Earth (again see Section on [Grids](#)).

The atmosphere is strongly multiscale in both space and time. In terms of spatial energy spectra, the largest scales are energetically dominant, but spectra are rather shallow, implying that, whatever the resolution of an atmospheric model, there is significant dynamical variability near the resolution limit, which requires careful handling by numerical methods, and on unresolved scales, which must be represented by 'subgrid models.' The atmosphere also supports dynamics with a huge range of timescales. Care is needed in modeling fast processes to ensure that the numerical solution is stable (see Section on [Time Integration Schemes, Stability, Courant–Friedrichs–Lewy Criterion](#) below). On the other hand, fast waves (acoustic waves, and to a lesser extent, inertio-gravity waves) tend to be energetically weak, implying that the dynamics is often slowly evolving and close to hydrostatic and geostrophic balance. The chosen numerical method must be able to represent this balance accurately. Also, certain properties of the atmosphere evolve slowly, either in a Lagrangian sense (e.g., the moisture content of an air parcel in the absence of condensation and evaporation) or in a global integral sense (e.g., the total mass or energy of the atmosphere). Numerical methods should be able to capture these conservation properties accurately (see Section on [Conservation and Scale-Selective Dissipation](#) below).

Representation of Data

In a numerical model, the fields describing the three-dimensional state of the atmosphere (density, velocity,

temperature, etc.) must be stored in a computer as a finite set of values. There are several possible ways to do this.

- *Gridpoint representation.* In gridpoint methods, a field is represented by its values sampled at a finite set of points called the grid or mesh points ([Figure 1](#), top left).
- *Finite volume representation.* Each value stored in the computer represents the value of a field averaged over a finite volume or grid cell ([Figure 1](#), top right).
- *Finite element representation.* Each field $\phi(\mathbf{x})$ is represented as a series in terms of certain basis functions $\psi_i(\mathbf{x})$, and the coefficients $\hat{\phi}_i$ are stored in the computer ([Figure 1](#), bottom left):

$$\phi(\mathbf{x}) = \sum_i \hat{\phi}_i \psi_i(\mathbf{x}). \quad [1]$$

Usually the ψ_i are simple local functions such as piecewise polynomials that are nonzero only over a small number of grid cells.

- *Spectral representation.* As for finite element methods, each field is represented as a series in terms of certain basis functions, but here the basis functions are mutually orthogonal global functions. The simplest example in one dimension is a Fourier series representation, in which the basis functions are sines and cosines ([Figure 1](#), bottom right). For modeling the atmosphere on a spherical planet, a spectral method based on spherical harmonics is often used.

Some methods may be viewed in more than one way, for example as a finite volume representation for the purpose of looking at conservation properties but as a gridpoint representation for the purpose of calculating derivatives. In more than one dimension, combinations of the above methods can be used, e.g., spectral in the horizontal and gridpoint in the vertical.

The number of data values used to represent a field defines the model resolution: a greater number of data values corresponds to higher resolution and means that smaller-scale structures in the field can be represented. For a current-day global weather forecast model, a typical horizontal resolution might be a few tens of kilometers, while a typical vertical resolution might stretch from a few meters or a few tens of meters near the surface to 2 or 3 km in the stratosphere. Climate models generally have coarser horizontal resolution to make long integrations affordable.

Figure 1 Illustration of different discrete methods for representing the same one-dimensional function. Top left: representation by five gridpoint values (the sixth value is the same as the first because the function is periodic). Top right: finite volume representation as five grid cell averages. Bottom left: finite element representation in terms of five piecewise linear ‘wings hat’ basis functions. Bottom right: the first five Fourier components of the spectral representation of the function.

Round-Off Error, Truncation Error, Local Truncation Error, Consistency

Numerical solution of differential equations involves approximations and hence, inevitably, errors. Round-off error arises because a finite number of digits, and hence a limited precision, are used in storing numbers in a computer. On a typical workstation using standard precision, the round-off error is about ± 3 in the eighth decimal digit. For most purposes this error is so small as to be insignificant. However, the effects of round-off error can be greatly amplified in certain calculations; for example, when adding small numbers to large ones or when taking differences of nearly equal numbers.

The approximation of a continuous field by a finite set of data values and the approximation of derivatives or integrals by algebraic operations such as differences or sums is called discretization. The errors made in these approximations are called truncation errors. They are a function of the resolution of the model, and are usually much more significant than round-off errors.

The local truncation error is the residual obtained when the true solution of a differential equation is substituted into the discrete approximation of that equation. It is a measure of how well the discretization approximates the differential equation. For example, consider the one-dimensional linear advection equation

$$\frac{\partial \phi}{\partial t} + v \frac{\partial \phi}{\partial x} = 0, \quad [2]$$

where the advecting velocity v is a constant. Let us discretize on a uniform grid with spatial interval Δx and time interval Δt so that ϕ_j^n is the numerical approximation to ϕ at $x = j\Delta x$, $t = n\Delta t$.

Approximating the space and time derivatives by simple difference formulas gives, for example,

$$\frac{\phi_j^{n+1} - \phi_j^n}{\Delta t} + v \frac{\phi_j^n - \phi_{j-1}^n}{\Delta x} = 0. \quad [3]$$

If we substitute the true solution $\phi(j\Delta x, n\Delta t)$ in place of ϕ_j^n , etc., in eqn [3] and make use of Taylor series, we find the residual, i.e., the local truncation error, as $O(\Delta x) + O(\Delta t)$. In this example the discretization is said to be first-order accurate in space and time, because both Δx and Δt appear raised to the power one in the local truncation error. A discretization is said to be consistent if the local truncation error tends to zero as $\Delta x \rightarrow 0$ and $\Delta t \rightarrow 0$.

Spatial Discretization Methods: Finite Difference, Finite Volume, Finite Element, and Spectral

A huge variety of methods are available for approximating the spatial derivatives that appear in the governing equations. The different methods are related to how the data are represented. Finite difference methods are perhaps conceptually the simplest. Rearranging Taylor series allows the construction of approximate expressions for derivatives in terms of point values of the data. Equation [3] shows a simple example in which $\partial \phi / \partial x$ at $(x = j\Delta x, t = n\Delta t)$ is approximated by $(\phi_j^n - \phi_{j-1}^n) / \Delta x$. Higher-order accurate formulas and formulas for higher derivatives can also be derived.

Finite volume methods allow one to define a local or global integral of a predicted field, and so are natural when the emphasis is on integral conservation properties. The equations

are usually written in terms of the budget of each prognostic field for each grid cell, and the method is defined by constructing a suitable approximation for the flux of each field across each cell face.

For finite element and spectral methods, the objective is to determine how the coefficients $\hat{\phi}_i$ evolve in time. One way to do this is to require that the residual, that is, the error when the approximate solution [1] is substituted into the original differential equation, should be orthogonal to each of the basis functions. This approach typically leads to a set of simultaneous equations involving $d\hat{\phi}_i/dt$ multiplied by a sparse matrix called the mass matrix. Once these equations are solved for $d\hat{\phi}_i/dt$, $\hat{\phi}_i$ may be stepped forward using a suitable time integration scheme. Discontinuous Galerkin and spectral element methods are closely related to the finite element method and have also been used in atmospheric models.

For spectral methods, the basis functions are mutually orthogonal; therefore the mass matrix is diagonal and trivial to invert. On the other hand, nonlinear terms in the governing equations would be expensive to evaluate directly in terms of the spectral coefficients $\hat{\phi}_i$. Instead, it is simpler and more efficient to transform the model fields from a spectral representation in terms of $\hat{\phi}_i$ to a gridpoint representation in terms of ϕ_i to evaluate the nonlinear terms, and then to transform the result back into the spectral representation. The transforms can be carried out efficiently with the aid of a fast Fourier transform algorithm. This method is called the spectral transform method.

Grids

Because of the strong anisotropy of the atmosphere, atmospheric models are almost invariably constructed with a certain number of levels or layers in the vertical, with essentially the same horizontal grid structure at each level. Thus it makes sense to discuss the vertical grid structure and horizontal grid structure separately.

An obvious choice for the locations of the vertical levels is to place them at specified heights. However, in the presence of mountains, the bottom boundary condition is greatly simplified if the model levels are distorted to follow the terrain (Figure 2). It is common to define the levels to be more closely spaced near the bottom boundary, to better capture details of the atmospheric boundary layer.

Figure 2 Schematic showing three variants of a height-based coordinate and levels and how they vary in the vicinity of a mountain. Left: flat, terrain-intersecting levels; middle: basic terrain-following levels; right: hybrid levels that are terrain-following near the surface but become flat at high altitude.

The governing equations may be expressed in a variety of different vertical coordinates, and model levels chosen at specified values of the vertical coordinate. As well as height, example vertical coordinates include pressure, mass, potential temperature, and a Lagrangian vertical coordinate (i.e., one that moves with the flow), and their corresponding terrain-following variants. Each has its own advantages and disadvantages compared with a height-based coordinate and levels.

More accurate wave propagation and a more accurate representation of hydrostatic balance can be achieved by using a staggered vertical grid, in which different variables are interleaved rather than colocated. Two types of staggered vertical grid are widely used: those with the temperature variable at the same levels as the horizontal velocity components, commonly referred to as the Lorenz grid; and those with the temperature variable staggered with respect to the horizontal wind components, commonly referred to as the Charney–Phillips grid (Figure 3). The Charney–Phillips grid provides slightly more accurate wave propagation, while energy conservation is easier to achieve on the Lorenz grid.

For a limited area model, the simplest choice for the horizontal grid is a rectangular Cartesian grid. For a global model, a longitude–latitude grid is the simplest choice. However, the clustering of resolution near the poles creates additional difficulties related to stability, convergence of elliptic solvers (see below), and scalability on massively parallel computers. This has motivated the development of models with a variety of more uniform horizontal grids. Some examples are shown in Figure 4.

Staggered horizontal grids are possible, and can give increased accuracy in representing wave propagation and balance. Some examples of staggered rectangular Cartesian grids are shown in Figure 5. The commonest staggered grids are called the Arakawa A-, B-, C-, D-, and E-grids, after the work of Arakawa and colleagues who first studied their wave dispersion properties. Analogous staggering of variables is possible on more general polygonal grids such as those shown in Figure 4.

Time Integration Schemes, Stability, Courant–Friedrichs–Lewy Criterion

Given a solution at time $t = n\Delta t$ (and perhaps at earlier time steps), we need a scheme to advance the solution to time

Figure 3 Schematic showing the vertical placement of the prognostic fields for examples of the Lorenz vertical grid (left) and the Charney–Phillips vertical grid (right). u , v , and w are the velocity components, ρ is density, and θ is potential temperature.

$t = (n + 1)\Delta t$. A great many such schemes are possible. Consider the following differential equation to illustrate ideas:

$$\frac{d\phi}{dt} = R(\phi). \quad [4]$$

One of the simplest possible schemes approximates the time derivative by a forward difference:

$$\frac{\phi^{n+1} - \phi^n}{\Delta t} = R(\phi^n). \quad [5]$$

Equation [3] uses this time integration scheme. This is an example of an explicit scheme, so-called because the formula

may be rearranged to give an explicit expression for ϕ^{n+1} in terms of known quantities.

The scheme (5) is not very accurate. Greater accuracy can sometimes be obtained by using information from other time levels, giving a so-called multistep method. The leapfrog scheme

$$\frac{\phi^{n+1} - \phi^{n-1}}{2\Delta t} = R(\phi^n). \quad [6]$$

is one example. Adams–Bashforth schemes also fall into this category.

Another way to increase accuracy is via a multistage scheme. Here, intermediate solutions are computed at one or more

stages between step n and step $n + 1$. The Matsuno or forward-backward scheme is one example:

$$\frac{\phi^* - \phi^n}{\Delta t} = R(\phi^n); \quad \frac{\phi^{n+1} - \phi^*}{\Delta t} = R(\phi^*). \quad [7]$$

Runge-Kutta schemes are also popular multistage schemes.

An important consideration for time integration schemes is stability. There are several slightly different technical definitions of stability. For practical purposes, a scheme is unstable if it produces numerical solutions that grow in amplitude when the true solution does not grow. Explicit time integration schemes are typically stable only for sufficiently small Δt , that is, they are conditionally stable. Stable solutions for larger time steps can be obtained using implicit time integration schemes. A simple example is the trapezoidal or Crank-Nicolson scheme

$$\frac{\phi^{n+1} - \phi^n}{\Delta t} = \frac{1}{2} (R(\phi^n) + R(\phi^{n+1})). \quad [8]$$

Such schemes are called implicit because the unknowns ϕ^{n+1} appear in several places, and a system of (possibly nonlinear) simultaneous equations must be solved to step forward. See Section on [Elliptic Problems](#) below.

Stability often depends on the coupling of the spatial discretization and the time integration scheme, in particular on the satisfaction of the Courant-Friedrichs-Lewy (CFL) criterion. The CFL criterion states that a necessary condition for stability is that the numerical domain of dependence of the solution at any point in space and time should contain the physical domain of dependence. For simple schemes, such as (3), the CFL criterion often reduces to the requirement that the Courant number $c\Delta t/\Delta x$, where c is an appropriate wave or advective signal velocity, should be less than one.

Various issues must be taken into consideration when choosing a time integration scheme (in combination with a spatial discretization). The scheme should, of course, be stable, but at the same time it should not introduce excessive dissipation or damping of the solution. Phase and group propagation of all waves of meteorological interest should be accurately captured. Even waves that are not of direct interest (often the case for acoustic waves and sometimes inertio-gravity waves) must be captured well enough to represent adjustment toward balance. Multistep schemes may support computational modes, that is, numerical solutions that do not correspond to any solution of the original differential equation; some form of time filtering may be necessary to control them. Finally, the overall cost should be acceptable.

In practice, time integration schemes are often complex combinations of the kinds of scheme mentioned above. For example, early atmospheric models often used a leapfrog scheme (6) for the conservative wavelike terms combined with a forward scheme (like (5), but from step $n - 1$ to step $n + 1$) for dissipative terms, using each scheme on the terms for which it is conditionally stable. To avoid solving a global nonlinear system of equations, semi-implicit schemes treat a linearized subset of terms in the governing equations implicitly (like [eqn \[8\]](#)) and the remaining terms explicitly. Horizontally explicit, vertically implicit schemes treat only vertical derivative terms implicitly, so that only a relatively small system of equations needs to be solved for each vertical column. Finally, split explicit schemes are also popular. These avoid the need to solve

a system of simultaneous equations that arises with an implicit method while reducing computational cost by taking small time steps only for a subset of (relatively cheap) terms associated with fast waves and using longer time steps for the other (more expensive) terms.

Advection

The transport of some fluid property by fluid parcels is called advection. The importance of advection for fluid problems, and, in particular, the fact that many important quantities, such as potential temperature, potential vorticity, moisture, and long-lived chemical tracers often evolve slowly following fluid parcels – that is, they are approximately conserved in a Lagrangian sense – have led to a great deal of effort to develop accurate numerical methods for advection.

One approach to modeling advection is to combine an accurate approximation for the spatial derivatives (e.g., the $\partial\phi/\partial x$ term in [eqn \[2\]](#)) with an accurate approximation for the time derivative term (e.g., the $\partial\phi/\partial t$ term in [eqn \[2\]](#)). In this approach, better stability and accuracy is often obtained by using an upwind biased approximation for the spatial derivatives.

An alternative approach is to re-express the advection equation as

$$\frac{D\phi}{Dt} = 0, \quad [9]$$

where D/Dt indicates a derivative following a fluid parcel rather than at a fixed point in space. Semi-Lagrangian schemes follow this approach. For each gridpoint, x_j say, they first compute a departure point x_d , which is the location at step n of the fluid parcel arriving at x_j at step $n + 1$. The value of ϕ at the departure point ϕ_d^n is computed by interpolating the field ϕ^n . Then the arrival point value is set equal to the departure point value: $\phi_j^{n+1} = \phi_d^n$. Semi-Lagrangian schemes are widely used in atmospheric models because of their high accuracy, and because their stability is not limited by the advective Courant number, allowing longer time steps and making them very efficient.

It is often desirable to ensure that the numerical advection scheme does not lead to unphysical negative values of the advected field, or to spurious amplification of extrema (which could lead to spurious supersaturation in the moisture field, for example). Such a desirable property goes by a variety of names, including monotone, monotonicity preserving, total variation diminishing, shape preserving, or locally bounded. It can be achieved by suitable modifications to interpolation schemes or to fluxes, often referred to as limiters.

Elliptic Problems

Elliptic problems arise in atmospheric models when some form of balance is assumed, e.g., when determining the stream function from the quasigeostrophic potential vorticity, or when determining the pressure field for the Boussinesq or anelastic equations. They also arise when vertical vorticity and horizontal divergence are the predicted variables, and it is necessary to diagnose the velocity field from them via a stream function and velocity potential. Finally, the system of equations that

arises for the unknowns when using an implicit or semi-implicit time integration scheme typically takes the form of a spatial discretization of a Helmholtz problem

$$\phi^{n+1} - \nabla \cdot (\nu \nabla \phi^{n+1}) = \text{RHS}, \quad [10]$$

where RHS indicates known terms.

Spatial discretization of an elliptic problem leads to an equation of the form

$$\mathbf{M}\phi^{n+1} = \mathbf{B}, \quad [11]$$

where $\mathbf{M}$ is a sparse matrix and $\mathbf{B}$ is a known vector. Direct solution of eqn [11] is usually prohibitively expensive for three-dimensional problems. However, other methods are available.

If a spectral representation of ϕ was used and the basis functions could be chosen to be eigenfunctions of the Helmholtz operator, then $\mathbf{M}$ would be diagonal and the solution would be trivial. In practice the basis functions are usually chosen to be eigenfunctions of the horizontal part of the Helmholtz operator (for ν constant), e.g., spherical harmonics for a global model. Then eqn [11] separates into a number of much smaller problems whose matrices correspond to the vertical part of the Helmholtz operator; these can be solved by direct matrix inversion.

If a spectral method is not used, then eqn [11] may be solved iteratively. One type of iterative method improves ('relaxes') the solution at each gridpoint in turn, making a number of sweeps over the whole grid. Depending on the details of the relaxation, this gives rise to Jacobi, Gauss-Seidel, and successive over-relaxation methods. Convergence of these basic relaxation methods may be slow if the length scale $\nu^{1/2}$ in eqn [10] is large compared with the grid length. In this case, convergence can be greatly accelerated by using a multigrid method, in which some iterations are carried out on coarser grids than that on which the final solution is required.

Another type of iterative method finds a sequence of successively better solutions over a growing hierarchy of vector spaces, called Krylov subspaces, whose bases are generated by iteratively applying $\mathbf{M}$ to some starting vector. Depending on the details, this gives rise to methods such as conjugate gradient, biconjugate gradient, minimum residual, generalized minimum residual, and generalized conjugate residual with k steps. The convergence of Krylov subspace methods can often be greatly improved by use of an appropriate preconditioner. That is, the problem [11] is rewritten as

$$\mathbf{P}^{-1}\mathbf{M}\phi^{n+1} = \mathbf{P}^{-1}\mathbf{B} \quad [12]$$

or as

$$\mathbf{M}\mathbf{Q}^{-1}(\mathbf{Q}\phi^{n+1}) = \mathbf{B} \quad [13]$$

for some matrix $\mathbf{P}$ or $\mathbf{Q}$ whose inverse is easily calculated.

Conservation and Scale-Selective Dissipation

Good Lagrangian conservation properties can often be achieved in a numerical model by the choice of an accurate

advection scheme, as discussed above. Depending on the application, integral conservation properties may also be important. Conservation of mass of air, mass of moisture and chemical tracers, energy, angular momentum, entropy, and potential enstrophy (among others) have all been addressed by model developers. Conservation of mass is straightforwardly achieved by the use of a finite volume method for the density or tracer density equation. Other conservation properties typically require some special measures in the numerical methods, and may only be achieved approximately.

A variety of processes can lead to the growth of variability or 'noise' in a numerical model on marginally resolved scales. These include physically realistic processes such as the transfer of energy and potential enstrophy to different length scales through the nonlinearity of the governing equations, as well as numerical errors such as dispersion errors and aliasing (the misrepresentation of variability at one, unresolved, scale as variability at another, resolved, scale). Other contributors include the action of physical parameterization schemes, and small-scale forcing, for example, due to orography. To control such a build up of noise, all atmospheric models include some form of scale-selective dissipation that preferentially damps small scales. This may be in the form of extra dissipation terms explicitly added to the governing equations, or in the form of inherently dissipative numerical approximations. Care is needed to ensure that such dissipation is sufficient to control the buildup of grid-scale noise without leading to excessive damping or adversely affecting conservation properties.

Synopsis

The parameterizations of physical processes that cannot be explicitly represented by numerical weather prediction models are critical model components and their improvement is one reason why numerical models are becoming more skillful. Parameterization schemes relate the effects of the chosen physical process to the model variables using an algorithmic or statistical approach. Typical parameterization schemes used in operational forecast models represent the effects of shortwave and longwave radiation, cloud cover, soil–vegetation–water–atmosphere transfer, urban areas, planetary boundary layer, convection, microphysics, and orographic drag. Brief overviews of some of these parameterizations are provided, along with a comparison of scheme results to highlight recent advances and remaining challenges.

Introduction

Numerical weather prediction models are ubiquitous in meteorology and the atmospheric sciences. These models form the cornerstone of operational weather forecasting and are used to study a wide variety of phenomena from thunderstorms to the El Niño Southern Oscillation. Numerical models also are beginning to play a role in seasonal forecasting and are a key component in studies of global climate change. Arguably, the most important components of these models are the subgrid-scale parameterization schemes that represent physical processes the model cannot resolve explicitly. These parameterization schemes determine the amounts of shortwave and longwave radiation that reach the Earth's surface; the partitioning of energy into sensible and latent heat fluxes from the Earth's surface to the atmosphere; the evolution and depth of the planetary boundary layer (PBL); the development and evolution of clouds; and the amount of rainfall that reaches the ground. Parameterization schemes are important because they have a very large influence on the resulting model behavior. If one desires to improve model capability and/or model forecast skill, then one must have a deep understanding of model parameterization schemes.

The development of parameterization schemes follows the reductionist approach, whereby schemes are developed separately for individual physical processes and it is assumed that the sum total of all the schemes in a model is capable of representing the behavior of the atmosphere. The schemes almost always treat the effects of the subgrid-scale physical processes within the vertical column of each model grid cell (Figure 1) and only rarely deal with changes in the horizontal direction. The vertical projection of parameterizations is a natural outcome of the physical processes represented, which tend to rearrange mass and momentum in the vertical direction. Parameterization schemes relate the effects of the chosen physical process to the model variables using an algorithmic or statistical approach. The development of a scheme tends to occur independently of other schemes and often involves testing of scheme performance against observational data sets, which may be limited in geographic extent. When inserted into a numerical model, the scheme is then

assumed to produce reasonable results anywhere on the globe and likely for conditions in which it was never fully tested. However, the overall success of operational numerical weather prediction indicates that the reductionist approach has worked very well. The continued presence of forecast failures suggests that understanding the interactions between parameterization schemes may be needed to provide further forecast improvements.

The development of new parameterization schemes appears to be accelerating. Articles in American Meteorological Society journals with the word 'parameterization' in the title have more than doubled from 104 in the decade from 1980 to 1989 to 228 in the decade from 2000 to 2009. Community models, such as the Weather Research and Forecasting (WRF) model, allow users to select between multiple parameterization schemes for each different physical process contained in the model. This situation has both positive and negative aspects. The positive side is that a wise user can select parameterization schemes that are best suited for a particular problem being investigated. The negative side is that the selection of a poor parameterization scheme could lead not only to an inaccurate weather forecast but also to the wrong conclusion when conducting a phenomenological study. Thus, the need to understand parameterization schemes has increased and model users must accept greater responsibility to make good scheme choices.

The study of parameterization also opens a window for us to examine our most fundamental understandings of atmospheric processes. A physical process is distilled to its most essential components when put into a parameterization scheme, as only a limited amount of complexity is possible due to computational constraints. Each scheme starts from a set of assumptions that depend to some extent upon the configuration of the numerical model for which it is designed. A common assumption used by nearly all parameterization schemes is the horizontal grid spacing of the numerical model. As model grid spacing continues to decrease as computer power increases, some schemes are no longer needed and the assumptions behind other schemes may be violated unless the scheme is updated to function properly at the smaller grid spacing. This situation presents substantial

Figure 1 Conceptual illustration of a vertical column of a grid cell within a numerical weather prediction model. Some of the important parameterization schemes, including shortwave and longwave radiation, deep and shallow convection, planetary boundary layer, soil–vegetation–water–atmosphere transfer, and urban effects are shown.

challenges to the community as we seek to balance the benefits gained from smaller grid spacing with the costs associated with updating parameterization schemes.

One of the more significant changes in the past decade is the increased attention to parameterization and the more thoughtful verification and comparison of scheme behavior. In this article, a few of the more common parameterization scheme types found in numerical weather prediction models are briefly discussed to provide some perspective on the challenges to parameterization. Since it is impossible to discuss all the parameterization schemes available for a given physical process, the basic concepts behind the schemes are outlined and output from several schemes are compared to highlight the importance of these schemes to the resulting numerical forecasts. For all the parameterization scheme comparisons, the Advanced Research WRF model is used with all other parameterization schemes held constant and identical initial and boundary conditions. Thus, the differences described later are due to the cumulative effects of the different parameterization schemes on the model forecasts.

Shortwave and Longwave Radiation

Two of the most important and computationally expensive parameterization schemes for climate and weather models are the schemes that predict shortwave and longwave radiation. Shortwave radiation is produced by the sun, passes through the atmosphere where it is both absorbed and scattered, and eventually reaches the Earth's surface. Approximately 40% of the electromagnetic energy emitted by the sun is in the visible region of 0.4–0.7 μm , with 10% in shorter wavelengths

(ultraviolet) and 50% in longer wavelengths (near infrared). Some of the incoming shortwave radiation is reflected back to space, due to the albedo effect, with the remainder absorbed by vegetation and the ground surface. Rayleigh scatter dominates for the shorter wavelengths, producing the blue color of the sky, whereas absorption occurs in clouds for the longer wavelengths.

The surface albedo over land depends upon soil type, soil moisture, vegetation type and vegetation coverage, and human changes to the landscape. The albedo of vegetation and the amount of vegetation coverage change throughout the plant life cycle. Wet soils have a lower albedo than dry soils. In colder climates, newly fallen snow can produce an albedo near 0.9, which then decreases as the snow melts and ages. The albedo over water depends upon the solar zenith angle – the angle between a line pointing toward the sun and the vertical – with the albedo approaching 1 for large zenith angles and approaching 0 for small zenith angles. The presence of clouds also dramatically alters the albedo. Clouds reflect and absorb shortwave radiation and the reduction of shortwave radiation under overcast skies can be considerable. Aerosols created from sea spray, fires, dust, chemical reactions, boreal forests, pollution, and volcanic eruptions also influence shortwave radiation through absorption and scattering. Aerosols can act as cloud condensation nuclei for cloud droplets, thereby helping to create clouds and modifying the albedo.

The surface albedo in many models is determined by a database of land use type and is held constant throughout the forecasts. Satellite analyses and surface reports are used to create maps of snow cover. The presence and amount of cloud is either predicted explicitly by the model or parameterized using other model variables such as relative humidity and vertical motion. Aerosol optical depth is measured at the

ground and can be estimated by satellites, although not all models include aerosol effects.

Parameterization schemes for shortwave radiation have increased in sophistication in the past few decades. The shortwave irradiance is divided into direct and diffuse contributions, where the direct component is from photons that have not been scattered. Calculation of the direct component follows Beer's Law, with the irradiance at a specific frequency reaching a given vertical level related to the distance traveled through the atmosphere (path length) and the optical depth that depends upon the absorber characteristics and concentration in the layer traversed. Integration over all frequencies yields the total shortwave irradiance. Narrow- or broad-band approaches can be used for the integration over frequency and the correlated- k method, in which the absorption coefficients are rearranged into ascending order over a given frequency interval, can be used to increase integration speed and accuracy. Calculation of the diffuse component is much more difficult, owing to the effects of multiple scattering and leads to an integration over both frequency and zenith angle for upward and downward directed fluxes.

A comparison of two commonly used shortwave radiation schemes from a 6-h forecast valid at 1800 UTC 2 April 2006, produced by the WRF model using 20-km grid spacing, indicates that the amount of radiation that reaches the Earth's surface is similar over a majority of the model domain (Figure 2). Even under clear skies, however, differences often exceed 30 W m^{-2} . The largest differences stretch from the Gulf of Mexico northward to the Midwestern states in association with larger values of precipitable water, 1000–500 hPa mean relative humidity, and model-produced rainfall (Figure 3). These are areas where cloud cover is diagnosed in the model, thereby reducing the shortwave radiation reaching the surface. The maximum difference between the two schemes at any grid point is 770 W m^{-2} while the mean absolute difference over all grid points is 79 W m^{-2} . The larger differences in the two schemes are related to how they treat cloud effects.

Longwave (terrestrial) radiation is produced at the Earth's surface and extends from the near infrared through the infrared portions of the spectrum with a peak near $11 \mu\text{m}$. Numerous atmospheric gases absorb and emit longwave radiation, including carbon dioxide, water vapor, ozone, methane, and nitrous oxide. Some of these gases are well mixed in the atmosphere, while others can have large horizontal and vertical gradients. Other atmospheric gases such as nitrogen and oxygen are almost totally unaffected by infrared light. Clouds also are very efficient absorbers and emitters of longwave radiation, which is particularly important since clouds cover over half the globe at any given moment.

Parameterization schemes for longwave radiation are similar to those for shortwave radiation, although the range of frequencies that need to be integrated is larger and scattering effects can be neglected. A two-stream approach is used whereby the upward and downward radiative fluxes are calculated separately and either narrow- or broad-band methods are used to integrate the radiative transfer equation over all frequencies. The equations appropriate for calculating the longwave radiative flux are

$$F_U(z) = \int_0^\infty \pi B_\nu(0) \tau_\nu^f(z, 0) d\nu + \int_0^\infty \int_0^z \pi B_\nu(z') \frac{d\tau_\nu^f}{dz'}(z, z') dz' d\nu, \quad [1]$$

$$F_D(z) = \int_0^\infty \int_z^\infty \pi B_\nu(z') \frac{d\tau_\nu^f}{dz'}(z, z') dz' d\nu, \quad [2]$$

where F_U and F_D are the upward and downward fluxes through height z , B_ν is the Planck function, ν is frequency, and τ_ν^f is the diffuse transmission function defined over a hemisphere. The diffuse transmission function depends upon the concentration of the attenuating gas over the integration depth and its absorption coefficient, which is a function of temperature and pressure. The first term in F_U represents the attenuation of the longwave radiation emitted from the ground surface, while the second term represents the longwave radiation emitted by the atmosphere. The single term in F_D represents the longwave radiation emitted by the atmosphere. Longwave radiation parameterization schemes differ in how these integrals are calculated and how the absorption coefficients are handled.

Comparisons between line-by-line radiative transfer models and longwave parameterization schemes have led to numerous improvements, including the use of the correlated- k approach. However, as with the shortwave radiation schemes, differences between longwave schemes are most discernable when clouds are present (Figure 4). The largest differences between two longwave radiation schemes largely overlap the regions of largest differences in the shortwave schemes (Figure 2). Differences of up to 98 W m^{-2} in longwave fluxes are indicated, with a mean absolute difference of 11 W m^{-2} over all grid points.

Soil–Vegetation–Water–Atmosphere Transfer

Gradients in soil and vegetation conditions, as well as gradients in the radiation fluxes that reach the surface, lead to horizontal gradients in surface sensible and latent heat fluxes from the ground surface to the atmosphere. The partitioning of sensible and latent heat fluxes directly influences near surface temperature, moisture, and winds as well as the depth of the PBL. Strong horizontal gradients in sensible heat flux can lead to nonclassical mesoscale circulations, such as vegetation breezes, and may influence low-level cloud development. The harvesting of crops dramatically changes vegetation conditions over a matter of days, providing a clear human influence on near surface conditions. The presence of buildings and urban areas also influence the partitioning of the sensible and latent heat fluxes and can lead to the development of urban heat islands. The effects of urban areas are sometimes calculated in separate parameterizations owing to the importance of forecasts in urban areas to energy demand and the sheer size of the population that resides in urban environments.

The strong influence of vegetation on the partitioning of sensible and latent heat fluxes creates a number of challenges to land surface parameterization. The movement of water from the soil to the roots to the stomata in the leaves and hence to

Figure 2 Shortwave radiation flux (W m^{-2}) reaching the Earth's surface at 1800 UTC 2 April 2006 (6-h forecast) calculated using the WRF model with 20-km grid spacing with the (a) rapid radiative transfer model (RRTM) and (b) Goddard shortwave parameterizations. The difference (Goddard-RRTM) is shown in (c). Values indicated by color bars.

Figure 3 Fields of (a) precipitable water (cm), (b) 1000–500 hPa mean relative humidity (%), and (c) 1-h accumulated rainfall (inches) valid at 1800 UTC 2 April 2006 (6-h forecast) using the WRF model with the RRTM shortwave parameterization. Values indicated by color bars.

the atmosphere must be represented in both weather and climate models. Yet plants have developed strategies to minimize water loss. Whereas the need for plants to obtain carbon dioxide for photosynthesis drives the exposure of saturated plant tissues to the atmosphere, the majority of land surface models simply assume that the stomata will remain open until the water supply from the soil is cut off. Newer schemes are starting to include calculations of photosynthesis that directly influence vegetation transpiration.

Another challenge to land surface parameterization is the accurate depiction of the initial condition of the land and vegetation states. Soil moisture can have large variations over small distances due to changes in rainfall, soil type, terrain slope, vegetation, and soil conditions. Unfortunately, there are few *in situ* measurements of soil moisture and temperature, and satellite observations can only provide information on soil moisture in the first few centimeters below the surface. Thus, the initial soil moisture and temperature values often are provided by land data assimilation schemes that force a land surface parameterization with observations of rainfall, surface meteorological observations, and satellite estimates of incoming radiation. The use of observations to force the land surface parameterization is found to yield reasonable soil moisture and temperatures when compared against available observations. Vegetation conditions can change dramatically from season to season and year to year, with changes in the timing of spring green up to several weeks typical. Farmers also rotate their crops or leave the fields fallow, altering the vegetation type. While vegetation coverage and type can be estimated from satellite, many models use a monthly vegetation climatology that may differ significantly from conditions on the ground. One of the more important parameters in land surface models is the vegetation fraction – the fraction of the model grid cell where midday solar radiation is intercepted by actively transpiring vegetation. The vegetation fraction directly influences the latent heat flux by weighting the bare soil and canopy transpiration. Differences of 30% or larger between an interpolated monthly climatology of vegetation fraction and real-time estimates from satellite are quite common.

A comparison of two land surface schemes indicates that while the general patterns of sensible and latent heat fluxes are similar (Figure 5), differences of 100 W m^{-2} or more can be present at individual grid points. The pattern of latent heat flux matches well with the climatological vegetation fraction used by the schemes (Figure 6) with larger values of vegetation fraction leading to larger latent heat flux. In contrast, the regions with the largest values of sensible heat flux are located across the southwestern portion of the model domain and correspond with low values of vegetation fraction and larger values of shortwave radiation. Thus, the largest sensible heat fluxes occur where there is little vegetation, few clouds, and strong incoming solar radiation. The important role of vegetation is seen through binning the latent heat flux differences by the vegetation fraction value. Results indicate that the two land surface schemes yield the largest mean differences in latent heat flux for values of vegetation fraction less than 40% and greater than 60% (Figure 7). The differences are due to the different formulations for bare soil and canopy transpiration.

Figure 4 Longwave radiation flux (W m^{-2}) reaching the Earth's surface at 1800 UTC 2 April 2006 (6-h forecast) calculated using the WRF model with 20-km grid spacing with the (a) rapid radiative transfer model (RRTM) and (b) Geophysical Fluid Dynamics Laboratory (GFDL) longwave parameterizations. The difference (GFDL–RRTM) is shown in (c). Values indicated by color bars.

Figure 5 Sensible and latent heat fluxes (W m^{-2}) at 1800 UTC 2 April 2006 (6-h forecast) calculated using the WRF model with 20-km grid spacing. Sensible heat fluxes from the (a) NOAA, (b) Rapid Update Cycle (RUC), and (c) their difference (RUC–NOAH). Latent heat fluxes from the (d) NOAA, (e) RUC, and (f) their difference (RUC–NOAH). Values indicated by color bars.

Over bare soil, a common approach is to define the latent heat flux Q_{EB} as

$$Q_{EB} = (1 - \sigma_f) \left(\frac{\Theta_1 - \Theta_w}{\Theta_{fc} - \Theta_w} \right)^a E_p, \quad [3]$$

where E_p is the potential evaporation, σ_f is the vegetation fraction (0–1), Θ_1 is the volumetric water content within the top-most soil layer, Θ_{fc} is the volumetric water content field capacity, Θ_w is the wilting point – the volumetric water content at which plants can no longer bring water out of the

Figure 6 Vegetation fraction (%) valid at 2 April 2006 as interpolated from a monthly climatology.

soil – and α is a scaling parameter. Thus, the latent heat flux is determined largely by the soil moisture value in the top-most soil layer. For the two schemes compared, α is set to 1 for the RUC scheme and is set to 2 for the NOAH scheme. While the calculations of E_p are not identical between the two schemes, the comparisons are consistent with the different values of α leading to larger latent heat fluxes from bare soil in the RUC scheme than in the NOAH scheme as seen in **Figure 7** for low values of vegetation fraction. The differences in latent heat flux for the higher values of vegetation fraction are due in part to the NOAH scheme including the effects of solar radiation, vapor

Figure 7 Mean flux difference (W m^{-2}) (RUC–NOAH) for sensible and latent heat flux values as a function of vegetation fraction (%) calculated using WRF model forecasts valid at 1800 UTC 2 April 2006 (6-h forecast).

pressure deficit, and air temperature on the canopy resistance, whereas the RUC scheme primarily uses only the root-zone soil moisture.

At first blush, one would think that calculating heat fluxes over water would be easier than over land, since ocean surface temperature varies slowly and there is no vegetation to complicate the parameterization. Indeed, for short range forecasts ocean water temperatures are often assumed constant. Challenges arise instead from the presence of waves, which have a large influence on the fluxes through alterations of the surface roughness. Sea spray is produced by wind gusts, bursting bubbles, and breaking waves, producing an atmospheric layer above the ocean in which water droplets evaporate and their temperatures come into equilibrium with the environment. This situation leads to alterations in the sensible and latent heat fluxes and produces a net drag on the airflow. Observations upon which to develop a parameterization are very challenging over the ocean, especially under high wind conditions.

Planetary Boundary Layer

The PBL is influenced directly by the Earth's surface and responds to surface fluxes with a timescale of an hour or less. Thus, the behaviors of the land surface and the PBL are tightly coupled. During the daytime, the boundary layer can extend to several kilometers above the ground and be fully turbulent throughout its depth, whereas at nighttime the boundary layer may be as shallow as a few tens of meters and turbulence is intermittent. These large changes in boundary layer depth during the diurnal cycle present unique challenges to parameterization.

The daytime PBL tends to be dominated by strong surface heat flux and vertical mixing due to large thermals – bubbles of buoyant air that start near the ground and rise into the boundary layer – that are roughly as wide as the boundary layer is deep. As these thermals impinge upon the top of the boundary layer they overshoot their level of neutral buoyancy and then sink back into the boundary layer bringing with them curtains of air from above. This entrainment of air from above the boundary layer into the boundary layer is a key factor in determining boundary layer depth and structure. The potential temperature is often well mixed (nearly constant with height) in the absence of clouds; moisture and momentum are not often well mixed. Surface sensible heat flux and entrainment both act to warm the boundary layer, while surface latent heat flux and entrainment often act in opposition since entrainment tends to bring drier air into the boundary layer. When clouds form within the boundary layer, the turbulence is modified and sometimes the turbulence within the cloud decouples from the turbulence within the rest of the boundary layer. Turbulence is intrinsic to the boundary layer and the largest boundary layer eddies provide turbulence its distinguishing characteristics.

The nocturnal PBL is dominated by longwave radiational cooling at the surface and episodic mixing events due to wind shear, drainage flows, and gravity waves. The nocturnal boundary layer is stable with potential temperature increasing with height. The lack of a strong controlling influence on the nocturnal boundary layer, and the ever-shifting interplay

between turbulent mixing and viscous and buoyant dissipation, leads to a challenging parameterization problem.

It is helpful to classify PBL parameterizations into two broad types: local and nonlocal closure schemes. Local closure schemes relate the unknown boundary layer variables to model variables at nearby vertical grid points. Many local schemes require the explicit prediction of turbulent kinetic energy, thereby adding a new variable to the model that must be integrated in time. The most significant concern with local schemes is that they assume mixing is related to the local turbulent kinetic energy, whereas observations indicate that large eddies produce most of the mixing. Nonlocal closure schemes relate the unknown boundary layer variables to model variables anywhere within and near the boundary layer. A nonlocal perspective often is shown to better explain the turbulence characteristics of a boundary layer. However, as with all parameterizations, a number of assumptions are needed to develop a nonlocal closure scheme that may not be well suited for all environments. Nonlocal schemes typically are used for daytime boundary layers and revert to a local scheme at night.

The difference between local and nonlocal closure can be illustrated using the turbulence diffusion equation for potential temperature (θ), in which the tendency due to boundary layer effects is expressed by

$$\frac{\partial \theta(z)}{\partial t} = \frac{\partial}{\partial z} \left[K_\theta(z) \left(\frac{\partial \theta(z)}{\partial z} - \gamma_\theta(z) \right) \right], \quad [4]$$

where K_θ is the eddy diffusivity coefficient and γ_θ is a correction to the local gradient that incorporates the contributions of the large-scale eddies. For a local closure scheme, the values of K_θ and γ_θ are complicated functions of the turbulent kinetic energy at the same vertical level. No information from lower or higher levels directly influences these terms. In contrast, for a nonlocal closure scheme the values of K_θ and γ_θ are vertical curve fits to values derived from large eddy simulations or observations, resulting in a specified vertical profile shape that depends upon the depth h of the boundary layer, the convective velocity scale w^* , and the entrainment coefficient k_e , often resembling

$$K_\theta(z) = w^* h \left(\frac{z}{h} \right)^{4/3} \left(1 - \frac{z}{h} \right)^2 \left(1 + \frac{k_e z}{h} \right). \quad [5]$$

Thus, the structure of the boundary layer, and in particular its depth and assumptions regarding entrainment, has a direct influence on the eddy diffusivity used in the parameterization. An equation for h is typically included in a nonlocal scheme in comparison to diagnosing boundary layer height from the turbulent kinetic energy as done within a local closure scheme.

Comparisons of five PBL schemes highlight the differences in scheme behavior and support the notion that local and nonlocal closure schemes produce consistent differences (Figure 8). The local closure schemes (MYJ, QNSE, MYNN) have lower mean boundary layer potential temperature, higher mean boundary layer mixing ratio, lower boundary layer depths, and higher values of surface-based convective available potential energy (CAPE) than the two nonlocal closure schemes (ACM2, YSU). One might hope that these consistent differences yield a clear conclusion that one type of scheme performs better than the other. Unfortunately, the comparison

results are not so clear. The local closure schemes better match the observations for boundary layer depth and surface-based CAPE, while the nonlocal closure schemes better match the observations of mean boundary layer potential temperature and mixing ratio (Figure 8). Based upon the temporal paucity of current standard observations with which to verify boundary layer structures, it is easy to argue that improvements to boundary layer schemes are greatly hampered by the lack of more frequent observations.

A more persuasive illustration of the differences in boundary layer schemes are predicted soundings from the 23-h forecasts of the same five schemes valid at Topeka, Kansas, on 2300 UTC 10 May 2011 (Figure 9). The two nonlocal closure schemes yield the deepest boundary layers as easily seen in the mixing ratio profiles. The local closure schemes predict a shallower boundary layer and much higher low-level mixing ratios. The effects of the PBL schemes on the mixing ratios between 800 and 700 hPa is dramatic and is routinely seen when multiple boundary layer schemes are compared. Also notice the differences in the low-level warm layer at the top of the boundary layer, which is not well predicted by any of the schemes.

Convection and Microphysics

Moist convection occurs in many sizes and shapes and plays a very large role in the success or failure of numerical model forecasts. Convection can be deep, such as thunderstorms or squall lines, or shallow as often found over the oceans off the west coasts of continents. Deep convection vertically spans much of the troposphere and produces precipitation, thereby acting to warm and dry the environment. Shallow convection vertically spans only a small portion of the troposphere and acts to cool and moisten the environment in the upper-half of the cloud and warm and dry the lower half of the cloud layer. Shallow convection produces no net warming or drying, as it is nonprecipitating.

The effects of convection can be treated implicitly using a convective parameterization scheme in which the effects of convection are parameterized prior to the occurrence of saturation at the model grid point. These schemes are used when model grid spacing exceeds 20 km. As model grid spacing drops below 4 km or so, then convection is treated explicitly by including parameterizations for microphysical processes that produce cloud water, rainwater, cloud ice, snow, graupel, and hail. A gray zone exists for model grid spacing between 4 and 20 km, since convective parameterization is needed to produce reasonable results, yet some of the assumptions used to develop convective schemes may no longer hold. In addition, some convective schemes are designed to work in tandem with a microphysics scheme as they act to encourage grid-scale saturation and the development of mesoscale circulations associated with stratiform convective regions.

There are a wide variety of convective parameterization schemes and numerous ways to classify their behavior. One can separate the schemes into deep-layer and low-level control schemes based upon the vertical extent of the forcing that controls the convective activity. Deep-layer control schemes often tie the development of convection to the creation of

Figure 8 Mean boundary layer parameters computed over 25 days at selected radiosonde sites across the eastern two-thirds of the United States from five WRF model forecasts that vary only by PBL scheme for 12–24-h forecasts valid 1200 to 0000 UTC using data from the storm-scale ensemble forecast (SSEF) during 2011. Parameters are (a) mean boundary layer potential temperature (K), (b) mean boundary layer mixing ratio (g kg^{-1}), (c) mean boundary layer depth (m), and (d) mean surface-based CAPE (J kg^{-1}). The number of soundings comprising the mean at each hour is shown in the bottom right of each panel. The open circle denotes the mean of the radiosonde observations at the approximate time of launch. Local closure schemes are MYJ, QNSE, and MYNN, while nonlocal closure schemes are ACM2 and YSU. All WRF forecasts started at 0000 UTC in the period 9 May through 10 June 2011. The SSEF uses 4-km grid spacing and is run by the Center for Analysis and Prediction of Storms.

CAPE such that convection immediately consumes the CAPE created by the model. Low-level control schemes allow for CAPE to be stored and transported before it is activated by the scheme as these schemes focus on how convection is initiated through the removal of convective inhibition. However, one could also distinguish between convective schemes based upon whether or not scheme behavior is sensitive to moisture or instability, or whether or not the scheme tendencies are static or dynamic. The complexity of convective forms and sizes makes

classifying convective schemes difficult and illustrates the breadth of parameterization approaches developed.

One of the more significant advances in the past decade has been the fairly rapid move toward convection-allowing models that only use a microphysics parameterization to represent convective effects. These models no longer need to use a convective parameterization, and so avoid the many well-known limitations associated with the parameterization of deep convection. Results indicate that convection-allowing

Figure 9 Skew- T log p diagram of an observed sounding taken at Topeka, Kansas at 2306 UTC 10 May 2011 (black line) and the corresponding profiles from five 23-h WRF model forecasts that vary only by PBL scheme. The horizontal lines to the right of the temperature trace show the diagnosed PBL height for each sounding. Local closure schemes are MYJ, QNSE, and MYNN, while nonlocal closure schemes are ACM2 and YSU. Forecasts produced by the 4-km SSEF system run by the Center for Analysis and Prediction of Storms.

models are much more capable of reproducing the observed behaviors of deep convection, such as the nocturnal propagation of convection across the central United States during the warm season, the development of surface cold pools and stratiform rain regions, and yield more accurate predictions of rainfall amounts. These models have also been very successful in producing realistic convective modes, or the forms of convection, such as an isolated thunderstorm, a supercell thunderstorm, a line of convective cells, or a bowing line of convective cells. However, we are also learning that the model forecasts are very sensitive to the microphysics parameterization.

A comparison of composite reflectivity forecasts from six microphysics schemes valid at 0200 UTC 10 June 2011 illustrates the differences often seen (Figure 10). All the schemes include predictive equations for cloud water, rainwater, ice, snow, and graupel, except for the Ferrier scheme that only has equations for cloud water, rainwater, and snow. There is general agreement that convection stretches from southwest to northeast but the intensity of the convective line and extent of the stratiform regions varies greatly among the schemes. Some only produce intense convection to the north, while others have intense convection along the entire convective zone.

Figure 10 Simulated composite reflectivity from 26-h forecasts valid at 0200 UTC 10 June 2011 calculated from six WRF model forecasts that vary only by microphysics scheme. The schemes are (a) Thompson, (b) WSM6, (c) WDM6, (d) Morrison, (e) Milbrandt-Yau, and (f) Ferrier. The observed composite reflectivity from the National Severe Storms Laboratory National Mosaic and Multi-Sensor QPE product is also shown. The Ferrier scheme is the only scheme that does not include graupel. The WSM6 and Ferrier schemes are single-moment bulk schemes, while the other schemes are double-moment bulk schemes for at least some of the hydrometeor types.

When compared to the observed composite reflectivity, none of the forecasts is a perfect match.

The associated 2-m temperature and 10-m wind forecasts valid at the same time again show dramatic differences between the schemes. The pools of evaporatively cooled downdraft air that spread out horizontally underneath precipitating clouds, commonly called cold pools, vary from being fairly weak in the Thompson scheme to very strong and extensive in the Ferrier scheme (Figure 11). The 10-m wind fields also show vastly different features, with the WSM6 and WDM6 schemes producing a strongly divergent wind field near the center of the convective zone and the rest of the schemes having a weakly divergent wind field in the same region. The column-integrated graupel mixing ratio also varies widely between the schemes, with the Milbrandt-Yau scheme having the largest coherent region of graupel.

The ability of four of these microphysics schemes to accurately predict rainfall location over many cases provides another interesting comparison. Results indicate that the Thompson scheme at forecast hour 30 has no coherent spatial bias in the location of rainfall forecasts in excess of 0.5 inches, whereas the other schemes predict rainfall too far to the south or southeast (Figure 12). These spatial biases likely are due to cold pools that are too strong due to excessive evaporation.

Future Directions

Forecasts from numerical weather prediction models have shown steady improvement over the past decades, leading to

people relying on forecasts more and more to help make personal and economic decisions. When significant snowstorms are predicted, airlines now cancel flights and move aircraft out of the affected region. When supercell thunderstorms are predicted, emergency managers take action to keep citizens safe by deploying storm spotters and responders ahead of the storms. The success of numerical weather prediction is due in large part to the improved parameterization schemes that are essential components of numerical weather prediction models. Without parameterization schemes, forecasts from numerical models would be nearly useless for meeting the weather forecast needs of society.

As model grid spacing decreases, the need for some parameterization schemes will disappear. At grid spacing below 4 km, there is no clear need for convective parameterization. At grid spacing below 50 m, there is no clear need for boundary layer parameterization. However, parameterizations for radiation, soil-vegetation-water-atmosphere transfer, and microphysics will always be needed as these physical processes operate on the molecular scale.

One of the challenges of the coming decade is how to handle the gray zones in which the physical process begins to be represented explicitly by the model but is not entirely represented. This is already occurring for convective parameterization for grid spacing below 10 km or so. But it also will occur for boundary layer parameterization when grid spacing approaches 1 km and the model begins to explicitly produce boundary layer circulations. These circulations represent the model trying to produce the large eddies observed in the

Figure 11 Fields of 2-m temperature (color filled by the scale on the bottom left), 10-m winds (full barb = 5 m s^{-1}), and column-integrated graupel mixing ratio (scale on the bottom right) from 26-h forecasts valid at 0200 UTC 10 June 2011 calculated from six WRF model forecasts that vary only by microphysics scheme. The schemes are (a) Thompson, (b) WSM6, (c) WDM6, (d) Morrison, (e) Milbrandt-Yau, and (f) Ferrier. The black line depicts the eastern edge of the surface cold pool.

Figure 12 Composite frequencies of observed rainfall greater than 0.50 inch relative to grid points forecasting rainfall greater than 0.50 inch at forecast hour 30 from SSEF members using (a) Thompson, (b) WSM6, (c) WDM6, and (d) Morrison microphysics parameterizations. Boldface dot in each panel marks the center of the composite domain. From Clark, A.J., et al., 2012. An overview of the 2010 Hazardous Weather Testbed experimental forecast program spring experiment. Bulletin of the American Meteorological Society 139, 55–74.

boundary layer and so will yield greater vertical mixing. Yet these large pseudo-eddies will not be able to account for all the mixing that occurs in the boundary layer, and so some additional boundary layer parameterization will be needed.

The challenges for radiation parameterization are different. Most parameterizations today assume that the radiation streams are directed vertically through a single model grid cell as depicted in [Figure 1](#). For a grid spacing of 40 km, this is a very reasonable assumption. As grid spacing drops below 10 km, however, the sunlight that reaches the ground in one grid cell actually passes through several neighboring grid cells. Similar arguments apply for longwave radiation. Thus, modifications to the radiation parameterizations clearly are needed as grid spacing decreases. The effects of terrain slope on radiation also are neglected in many models and deserve further attention.

The parameterization of microphysical processes faces yet another type of challenge. The past few years have seen the development of a number of double-moment bulk microphysical schemes in which both particle mixing ratio and particle number concentration are predicted. These double-moment schemes should allow the schemes to represent correctly the microphysical responses within a wider variety of environments, as particle mixing ratio and concentration can vary independently of each other. The challenge is that the number of tunable parameters in these parameterizations is large and verification data are limited. It may be that information on hydrometeor type, as can be estimated from dual-polarization radars, will be helpful in tuning double-moment microphysics schemes.

There are parameterizations for a number of other physical processes that have not been discussed. Parameterizations exist for fog, orographic drag, shallow convection, urban areas, and

the effects of wind turbines. These are all valid physical processes or effects that may be needed in a numerical model to increase its capability or forecast skill. The need for accurate parameterizations to propel advances in forecast skill suggests that continued and increased attention to model parameterization will be needed.

Synopsis

The state of the art of parameter estimation in atmospheric sciences is discussed. It is common in numerical weather prediction models to find parameterizations to represent subgrid-scale atmospheric processes such as radiation, cloud microphysics, convection, and turbulence. According to a widely accepted opinion, errors in such parameterizations are major contributors to model error. Parameter estimation aims to reduce such errors by utilizing atmospheric observations within the data assimilation framework. Although early work on parameter estimation mostly utilized variational techniques, with the advent and progress of ensemble-based data assimilation systems, an increasing number of parameter estimation studies based on ensemble-based techniques have recently emerged. The goal here is to highlight the state of the art in parameter estimation through the lens of these most recent atmospheric science publications.

Introduction

Parameter estimation in the field of atmospheric sciences refers to the determination of the best values of certain parameters in a numerical model through data assimilation or other similar techniques. The practice therefore is intimately tied to addressing model deficiencies due to inaccurate parameters. The approach is sometimes also referred to as the inverse modeling problem, although, from the viewpoint of parameter estimation, the distinction is mostly semantic. In some publications, one also encounters the alternative term parameter identification.

Parameters in numerical models can be part of processes that are either explicitly resolved or parameterized at the sub-grid scale. In the former, parameters are part of the model dynamical core of a model and are directly related to the physical changes in momentum and heat. Some examples of such parameters are the angular speed of the rotation of the Earth, the gravitational acceleration, the gas constant for dry air, and the specific heat of dry air at constant pressure. Such parameters are generally associated with universal physical processes and their values are well known with high accuracy.

In the latter case, subgrid-scale parameterizations can lead to large numerical model errors. This is due to two main reasons: (1) limited understanding and observations of the processes lead to large uncertainties in parameter values that quantify these processes; and (2) crude representation of the parameterized processes within one grid volume (or spectral truncation wavelength) leads to parameters that represent processes of multiple spatial and temporal scales. In numerical models, the most common subgrid-scale processes that are parameterized include turbulence in the planetary boundary layer (PBL), moist convection, phase changes of water (microphysical processes), and radiative transfer between the Earth's surface, atmosphere, and space. Each of these has a class of parameterizations with multiple proposed schemes (algorithms). These parameters are not known with high accuracy and must be estimated.

One can therefore envision two main purposes for doing parameter estimation. On the one hand, detailed and targeted observations and advanced data assimilation techniques can be

used to gain a better understanding of the parameterized physical processes themselves. This would aid in the tuning/calibration of numerical models during their development. If a numerical model becomes operational, one can also perform a similar procedure by augmenting the model state with the parameters to be estimated. Although both approaches are procedurally similar, in the former, one is more concerned with better understanding of the physical processes themselves, whereas the other aims to improve numerical forecasts through data assimilation by acknowledging that forecast errors are due to uncertainties in both the initial conditions and the model.

The early literature of parameter estimation in atmospheric sciences has generally focused on the use of variational data assimilation schemes. More recently, and with the proliferation and success of ensemble-based data assimilation systems in providing high-quality analyses at a wide range of atmospheric scales, an increasing number of studies based on these techniques have emerged. The goal here is to summarize the state of art in parameter estimation through the lens of these most recent studies.

Parameter Estimation Methodology

The general methodology of parameter estimation follows closely that of state-only data assimilation. Therefore, further reading in variational and ensemble-based data assimilation techniques are strongly recommended.

The first step in parameter estimation generally involves obtaining an augmented state vector that consists of both the state (control) variables and the parameters to be estimated. Since, by definition, there is no dynamical feedback from the model state to the parameters, the traditional algorithms of data assimilation are needed to be supplemented by specific measures so that optimal solutions for the parameters can be obtained. In variational data assimilation, explicit penalty terms are included in the cost function for parameters. Furthermore, in four-dimensional data assimilation, the adjoint model equation is augmented by an explicit term that involves the parameters. In ensemble-based data assimilation, appropriate parameter perturbations are introduced to obtain

one-way covariance information between parameters and the observed model state. Additionally, measures are taken to maintain sufficient parameter spread throughout data assimilation cycles.

In **Figure 1**, the general methodology of parameter estimation in a simplified schematic is illustrated. **Figure 1(a)** shows how a first guess that is sensitive to parameter perturbations is generated. First, the numerical model is advanced using perturbed parameters. In ensemble-based techniques this is achieved by advancing each ensemble member using a perturbed parameter value. Here, it is also assumed that there exists initial condition uncertainty, as it is standard in all data assimilation applications (hence the distribution in the ‘initial state’ balloon). In variational techniques, a ‘first guess’ parameter value is used to obtain the first guess for the model state. At this stage, observation operators are also applied to the first guess model state to obtain the first guess in observation space. In the second stage (**Figure 1(b)**), regression is carried out between the first guess and the parameter to be updated, to obtain a linear statistical relationship between the (observed) model state and parameters. In ensemble-based techniques, this involves the computation of sample covariances between observations and parameters. In variational techniques, adjoint models are used. Finally, the update is performed (**Figure 1(c)**) to obtain a new parameter value informed by the latest available observations. In ensemble-based techniques, this is done by projecting observation-first-guess differences onto the parameter space through the regression relationship. In variational techniques, a cost function minimization procedure that accounts for parameter variability is applied. It is also common to repeat this workflow in subsequent analysis cycles where model advances take into account the updated parameter values.

Parameter estimation is generally an extension of data assimilation in terms of its methodology. At the same time, it is unique in that there is only a one-way dynamical interaction between parameters and the model state. In other words, there is an increased possibility of low signal-to-noise ratio between parameters and observations in the presence of potentially strong dynamical interactions within model state variables themselves. In the next section, issues related to the difficulty of extracting useful information from observations to successfully update parameters are discussed in more detail.

Parameter Identifiability

Parameter estimation is, in essence, the problem of inverse mapping from model space to the space of parameters. In the atmospheric science literature, the term parameter identifiability has been used to denote how easy it is to find unique solutions of the inverse problem for unknown parameters from available observations of the model state. An argument is made that nonuniqueness and instability of the identified processes may contribute to the ill posedness of the problem. A more categorical explanation for parameter identifiability argues that three factors can be thought to contribute to it (see **Figure 2**, for a schematic illustration):

- Observability:** Changes produced by parameter variations do not necessarily project sufficiently strongly onto model/observation space. Strictly speaking, this may be due to both insufficient model sensitivity to and/or incompatible model-observation mapping with the parameters. The end result of realistic measurement errors leading to unrealistically large changes in estimated parameter values is the same. Lack of observability is illustrated in **Figure 2(a)** by the relatively flat slope of the regression line between the observed model state and parameters. In such a scenario, small observation differences are projected onto large parameter differences and may result in unphysical or unrealistic parameter values in the update.
- Simplicity:** Sometimes, even with sufficient model sensitivity, the mapping between the parameter space and model space can be such that a simple one-to-one relationship does not exist between the model output and the parameter to be estimated, which is generally caused by the nonlinearity in how the model responds to the expected parameter variations. In such situations, a unique solution may not exist to the inverse problem and the optimal parameter value may never be found. Lack of simplicity is illustrated in **Figure 2(b)** by the quadratic relationship between the observed model state and parameters. If the parameter space is not carefully constrained (i.e., the regression is limited to only one side of the quadratic relationship), the probability that the same observation differences are projected onto multiple distinct parameter

Figure 1 Illustration of the typical workflow of parameter estimation (using the ensemble method as an example). (a) Forward model. (b) Regression. (c) Update. Symbols α and Y represent the parameter to be estimated and the observation variable, respectively.

Figure 2 Illustration of types of parameter identifiability and how they can negatively impact successful parameter estimation. (a) Observability. (b) Simplicity. (c) Distinguishability. The thick curves in the panels represent the statistical regression relationship between parameters and observed state. Thin dashed lines represent selected parameter–observation pairs on the regression curves.

differences is increased, which can result in unrealistic parameter updates.

- c. *Distinguishability*: In other situations, various parameters may have similar aggregate effects on the model state. Therefore, observations related to the involved model output may lead to adjustments in the wrong set of parameters. Lack of distinguishability is illustrated in [Figure 2\(c\)](#), where very similar statistical relationships exist between the observed model state and two different types of parameters. In such a situation, given model response may be interpreted as being the result of perturbations in a wrong parameter, causing certain parameters to be updated toward unrealistic values, whereas those that should be updated remain mostly unchanged.

Successful parameter estimation is intimately linked to whether and how each of these factors is addressed. For example, observability implies that careful analysis must be carried out to ensure that the model exhibits sufficient sensitivity to the parameters to be estimated. At this stage, it is also imperative to choose variables that best reflect the sensitivity between model space and parameter space. Next, the proposed parameter space must be carefully examined to avoid non-simple observation–parameter relationships. Finally, when multiple parameters are estimated, cross correlations among the parameters must be carefully identified so that parameters that induce similar effects on the observed fields are eliminated. Only when all of these conditions are met, sufficient parameter identifiability can be achieved and successful parameter estimation can be performed. Some suggestions to improve identifiability are (1) change the observing system (i.e., address observability); (2) modify the model to eliminate the source of nonuniqueness (i.e., address simplicity); or (3) altogether modify the construction of the inverse method, which can be achieved by introducing new information to distinguish and avoid the behavior in the modeled processes that result in the nonuniqueness in the first place.

When parameter variations are considered in the context of uncertain initial and boundary conditions, sensitivity of the model state to parameters can decrease substantially, leading to heightened identifiability issues. This can be investigated

through the magnitude and linearity of the signal in the ensemble spread due to parameter perturbations. If lack of identifiability is detected, scaling parameter perturbations to increase the resulting ensemble spread could be helpful, but the positive effects would be unavoidably constrained if the linearity in ensemble spread is limited. Multiple, simultaneously uncertain parameters are also argued to be a source of negative impact on identifiability.

Earlier studies have investigated parameter identifiability mostly in the context of model sensitivity. Some studies approached identifiability both with the use of a response function and correlations between model output and uncertain parameters. A response function can be constructed to represent the mean-square distance between the model solution and observations averaged over all observation points. Normalizing then by observation variance provides a metric that allows for the comparison of model response as a result of various parameter perturbations. Computing the response function in observation space also addresses the observability aspect of identifiability. Another metric to investigate sensitivity is root-mean-squared correlation, which represents the magnitude of spatially averaged absolute sample correlation between the model state and parameters. The root-mean-squared correlation metric can also be extended to observation space to account for the observability aspect.

Other Challenges for Parameter Estimation

Besides the difficulties arising from identifiability issues, other challenges also exist for parameter estimation. One such important problem arises from the fact that parameters in a numerical model are not ‘dynamical’ by definition, by which it is meant that there is no feedback from the evolving model state back to parameters. In ensemble-based data assimilation, this creates the immediate problem of filter divergence: When the ensemble spread becomes exceedingly small, the first guess is given increasing weight by the data assimilation scheme, which results in new observations to have less weight on the analysis. Without dynamical feedback, parameter spread is destined to become small enough to lead to filter divergence unless explicit measures are taken to maintain the desired

level of ensemble spread in the parameters to be estimated. A common such measure is to ‘inflate’ analysis variance when it drops below a threshold level.

The other aspect of the nondynamical nature of model parameters is that they are generally specified ‘globally,’ i.e., they are assigned the same values over the entire computational domain of the model. In real-data applications with large, three-dimensional observational datasets, this results in the overdetermination of parameters and manifests itself in the form of excessive noise in updated parameters (updated parameters that appear to follow random walk). To counter this issue, one method, ‘spatial updating’ updates the parameters first horizontally as two-dimensional arrays using covariance localization, and then uses spatial averaging to obtain the updated global parameter values. Another approach is a data selection technique, which uses only a certain subset of observations that exhibit the largest ensemble correlations with the parameters.

When simultaneous state and parameter estimation is carried out, it has been shown by some that the state estimation errors dominate the uncertainties of the model state during the early stages of data assimilation so that the covariance information between the model state and parameters becomes unreliable. To remedy the situation, some studies used a delayed approach in which parameter estimation after a number of data assimilation cycles when the model state is likely to be constrained by observations, and covariances between the model state and parameters are likely to be reliable. Other studies chose not to update the state at all, instead focusing on updating parameters, and approached the filter divergence and overdetermination issues by assimilating observations individually at their exact time. The final global parameter value is then achieved by averaging over time and ensemble members.

Other challenges to successful parameter estimation pertain to the lack of knowledge on how best to sample parameter space. In most situations, suitable values of parameters are barely known and there is very little knowledge, if any, on the bounds and the nature of uncertainty that surrounds them. Although, as demonstrated by some studies, parameter uncertainty can take many shapes and forms in the form of non-Gaussian, multimodal distributions, in more realistic situations, such assumptions are difficult to make. This has generally led to the assumption of prior parameter distributions with limited information content, which generally takes the form of bounded uniform distributions or Gaussian distributions. However, since parameter values are generally expected to remain bounded and positive definite, Gaussian prior probability density functions (PDFs) are not always suitable choices. Approaches in the literature have varied to address these situations; methods such as transforming parameters logarithmically to mimic log-normal PDFs, assumption of beta distributions that are naturally bounded, and trigonometric transformations for bounded parameters are used.

As the number of parameters simultaneously estimated increases, a new issue also arises to effectively sample the multidimensional parameter space in an ensemble of limited size. Though most studies sample parameters independently from respective assumed prior PDFs, this does not necessarily guarantee that the joint parameter space is effectively sampled. One method to increase the effectiveness of sampling, the

Markov chain Monte Carlo algorithm, revisits high-probability regions of the parameter space in an iterative manner. Although this technique reduces the computational burden of effective sampling by a few orders of magnitude, for sufficiently many parameters, the technique may still be computationally unfeasible with complex numerical models. As an alternative, a Latin hypercube sampling strategy is suggested, which works in a normalized bounded space but provides independent parameter distributions with even sampling. These samples can then be transformed into any other PDF if nonuniform distributions are to be assumed.

Another challenge for parameter estimation arises from the nature of the complex and highly nonlinear relationship between individual parameters and the aggregate model response to them. In many situations, the same parameters simultaneously impact various processes, and the interactions among the processes make isolating individual impacts difficult. One proposed approach assigns multiplicative weights to the processes that contribute to the total outcome of a parameterization scheme, and introduces uncertainties to these weights. The advantage of this approach is that it is a natural way of looking at model error, in the sense that individual processes themselves are better understood physically and therefore lend themselves suitably to a subjective assessment of the misrepresentation of the parameterized aspect of the model. Furthermore, the additive nature of the processes themselves may prove advantageous in obtaining a linear model response to the perturbations of the multiplicative weights.

Future Advances

Research in parameter estimation is likely to advance on several avenues. First of all, studies that systematically investigate all dimensions of parameter identifiability are needed to obtain a complete picture of the challenges and limitations facing parameter estimation. Comparisons between parameter-related model sensitivity and initial condition- or boundary condition-related model sensitivity should be carefully made to take into account the timescales at which these various sources of sensitivity act upon the atmospheric state. For fair comparison, it is also advisable to note that model sensitivity to initial or boundary conditions is the result of perturbations that are usually obtained from continuously cycling data assimilation systems that do not account for parameter uncertainty, whereas, for practical reasons, parameter perturbations can only be introduced to the most recent initial and boundary condition ensembles.

There is also a need for a unified vision for ‘correlation localization’ that places the updating of state variables and parameters on a common ground. In state-only data assimilation, it is natural to visualize the influence of observations onto the model state in geographical space. For global model parameters, such a natural localization space does not exist. Although some studies have proposed ad hoc techniques to manage this dichotomy, a systematic approach that puts on equal ground the localizations for model state and model parameters has yet to emerge.

Finally, a fundamental shift from focusing on individual parameters, whose effects on the model state are usually

obscure because of the many dependent nonlinear processes, toward focusing on those actual processes that contribute to the particular subgrid-scale parameterizations may be prudent. It is possible to control the contributions from these individual processes by assigning multiplicative weights to their final output that are to be estimated. This philosophy also enables parameter estimation to become a more holistic approach to counter model error. After all, it may be more difficult to justify parameter estimation as a legitimate means of treating model error when estimated parameters are usually empirical and not well observed. When the focus shifts to the processes themselves, the uncertainty can be expressed in the natural space of known physical processes and the estimation may then effectively inform on the relative importance of individual processes under observed atmospheric conditions.

Summary

The state of the art of parameter estimation in atmospheric sciences is reviewed. Parameter identifiability, defined as the ease of finding unique solutions of the inverse problem for unknown parameters from available observations of the model state, is composed of the three dimensions of observability, simplicity, and distinguishability. The major challenges in parameter estimation are discussed as the nondynamical nature of model parameters, difficulty of updating globally specified parameters using spatially and temporally varying observations, distinguishability in the presence of initial and boundary condition uncertainty, lack of knowledge of the probabilistic nature of parameter uncertainty, and effective sampling of multidimensional parameter space. Some research directions for the near future are suggested.

Further Reading

See Navon (1998) for a comprehensive review of parameter identifiability and early literature on variational parameter estimation. Zhu and Navon (1999) provide some further technical details on the variational approach to parameter estimation. Good examples for recent studies on ensemble-based parameter estimation are Aksoy et al. (2006a,b), Tong and Xue (2008a,b), Hu et al. (2010), Jung et al. (2010), Godinez et al. (2012), Posselt and Bishop (2012), and van Lier-Walqui et al. (2013).

Nielsen-Gammon et al. (2010) discuss in detail the three dimensions of parameter identifiability. All three factors are evaluated there for various parameters of a PBL parameterization scheme: observability is deduced from the magnitude of ensemble standard deviations of model fields when individual parameters are perturbed, simplicity is deduced from the nature of scatter plots between model fields and individual parameters, and distinguishability is deduced from the overall level of correlations between model fields and individual parameters.

Posselt and Vukicevic (2010), using a one-dimensional model of convection and cloud microphysics, employed the Markov chain Monte Carlo approach to effectively sample the high-probability regions of parameter space spanned by multiple parameters. That way, they were able to obtain joint parameter-state PDFs, which, in some cases, exposed relationships that were highly nonlinear and multimodal, resulting in parameter identifiability issues.

Hacker et al. (2011) investigated parameter identifiability in the presence of uncertain initial and boundary conditions. The limitations to identifiability from simultaneous uncertain parameters are studied by Nielsen-Gammon et al. (2010), Posselt and Vukicevic (2010), Tong and Xue (2008b), and Aksoy et al. (2006a). To investigate sensitivity, Tong and Xue (2008a) suggested a response function and correlations between model output and uncertain parameters, whereas Aksoy et al. (2006a) used the metric root-mean-squared correlation.

Aksoy et al. (2006a) introduced the method of inflating parameter variance when it drops below a threshold level (also see Tong and Xue, 2008b; Jung et al., 2010; Zhang et al., 2012). The two counter measures for the overdetermination problem when estimating global parameters, the spatial updating method and the correlation-dependent data selection technique, were introduced by Aksoy et al. (2006a) and Tong and Xue (2008b), respectively. Jung et al. (2010) and Zhang et al. (2012) used the delayed parameter estimation approach to improve the sensitivity of the model state to multiple, simultaneously uncertain parameters. Godinez et al. (2012) chose to only update the parameters and used the technique of updating parameters at their exact time. To obtain prior distributions for bounded parameters, Tong and Xue (2008b) introduced logarithmic transformations, Hacker et al. (2011) applied beta distributions, and Nielsen-Gammon et al. (2010) used trigonometric transformations. The two methods to effectively sample the multiple parameter space, the Markov chain Monte Carlo algorithm, and the Latin hypercube sampling strategy, are suggested by Posselt and Vukicevic (2010) and Hacker et al. (2011), respectively.

van Lier-Walqui et al. (2013) proposed the process approach, where the weights of process outcomes are estimated rather than empirical parameters themselves.

Synopsis

Clouds are important for weather forecasting and climate prediction not only for their direct role in the hydrological cycle, but also for their interactions with radiation and the dynamics of the atmosphere. The formation and dissipation of clouds depends on the interaction of many small-scale processes, which must be parameterized in atmospheric models. General concepts of cloud parameterization and the hierarchy of approaches commonly used over the years are discussed, as well as contemporary issues for cloud scheme development.

Introduction

At any given time, clouds cover between 60 and 70% of the globe and for most of mankind they are an everyday experience. Clouds exert various influences on the Earth–atmosphere system, of which the most important are:

- modification of the radiative fluxes in the atmosphere and at the Earth's surface;
- release and consumption of latent heat related to phase changes of water either directly inside the clouds or in precipitation generated in them;
- transport of heat, moisture, momentum, and atmospheric trace constituents over large distances in the vertical in convectively generated clouds; and
- modification of the surface hydrology through precipitation generated in clouds.

For a more detailed discussion of these cloud effects the reader is referred to other articles in the encyclopedia (*see Clouds and Fog: Classification of Clouds; Climatology; Measurement Techniques In Situ. Mesoscale Meteorology: Convective Storms: Overview. Radiation Transfer in the Atmosphere: Cloud-Radiative Processes*) and in the Further Reading section at the end of this article.

Given the importance of the various influences clouds have in the evolution of both the atmosphere and the surface, it is immediately obvious that these effects need to be included in atmospheric models that are used for the simulation of climate and the prediction of weather. As described in the articles dealing with general circulation models (GCMs) and numerical weather prediction (*see Numerical Models: General Circulation Models; Regional Prediction Models*), these models seek numerical solutions to the hydrodynamic equations that govern atmospheric motions.

Various numerical techniques can be applied to achieve this goal, but all of them ultimately involve splitting the area over which the model is applied into 'boxes' of finite size in both the horizontal and the vertical. While the continuous differential equations describe atmospheric motions on all spatial and temporal scales, their discrete form can only describe processes on spatial scales of the order of twice the grid length or larger. Processes that occur in clouds cover a wide range of spatial

scales, from micrometers for the condensation and evaporation of individual cloud droplets, through a few hundred meters in the case of fair weather cumulus clouds, up to several hundred kilometers for the cloud systems associated with extratropical baroclinic systems. Hence, describing the detailed dynamics of individual clouds would require model grid box sizes on the order of meters or less. Current computing power as well as difficulties in finding the necessary initial conditions at these spatial scales prohibit the use of such grid box sizes in global atmospheric models. In reality, typical horizontal grid lengths in contemporary global models range from the order of 10 km in numerical weather prediction applications to more than 250 km in climate modeling. Processes that act on scales smaller than these grid sizes are normally referred to as subgrid-scale processes and are, per se, not represented in the solution of the finite difference equations. Many of these processes do, however, affect the dynamic and thermodynamic states of the atmosphere on larger spatial scales. Obvious examples are the large amounts of water vapor, heat, and momentum that are transported by turbulent and convective motions. Since an explicit description of the subgrid-scale processes is prohibited, only their statistical effects on the grid box-mean state can be taken into account. Since the numerical solution of the model equations allows the atmospheric state to be known only on scales on the order of the grid box size, the description of these statistical effects has to be expressed in terms of those scales. The technique involved is generally referred to as parameterization.

To describe the main effects clouds have on the atmosphere as outlined above, the following cloud-related quantities need to be known:

- horizontal coverage of cloud, normally referred to as cloud fraction;
- vertical extent of the clouds;
- sources and sinks of cloud condensate including condensation, evaporation/sublimation, and conversion into precipitation and fallout;
- phase of the condensate;
- particle size and shape;
- in-cloud distribution of condensate; and
- amounts of heat, water vapor, and momentum that are transported in convective clouds.

This list implies scales much smaller than the typical resolution of most atmospheric models. The problem of representing clouds in large-scale atmospheric models is therefore one in parameterizing their overall effects on the resolved scales.

There are a number of problems to be overcome in the parameterization of clouds. First, there exists a variety of cloud types, such as stratocumulus clouds at the top of convective boundary layers, vast cloud systems associated with extratropical disturbances, deep convective systems that may or may not be organized, and upper-tropospheric cirrus clouds. These different cloud types are formed, maintained, and dissipated by different physical processes, such as convection, radiative cooling, small-scale turbulence, large-scale ascent or descent, and cloud microphysical processes that lead to the generation of precipitation. Many of these processes are poorly understood and act on scales smaller than those resolved in a large-scale model, which makes them the subject of physical parameterization themselves. Furthermore, the radiative effects of clouds depend on a large number of different cloud parameters that all need to be described accurately to ensure their correct treatment in the radiation parameterization.

It is worthwhile pointing out that, because of their distinctive properties in terms of significant small-scale heat, water vapor, and momentum transport, cumulus and cumulonimbus clouds have been recognized as being of particular importance. This has led to (an artificial) separation of the description of the vertical transport and condensation effects from the radiative effects of convective clouds in what is known as cumulus convection parameterizations. As will be briefly discussed below, recent efforts in improving cloud parameterizations involve attempts to overcome this artificial split between convective and more 'stratiform' cloud processes. Furthermore, the details of the radiative transfer in clouds are normally dealt with in radiation parameterizations. Thus, typical cloud parameterizations need to:

1. describe the generation and dissipation of clouds and the precipitation formed in them; and
2. provide the radiation parameterization with the necessary information to evaluate the cloud effects on the radiative fluxes, most prominently the area coverage and cloud condensate content.

Before a brief overview of how the problem of cloud parameterization can be addressed, some general concepts for any type of cloud parameterization will be outlined.

General Concepts in Cloud Parameterization

The sizes of many of the observed clouds are often significantly smaller than the typical sizes of model grid boxes in GCMs. Even on integration over all individual clouds in an area comparable to those grid sizes, one finds from observations that often the area is only partially covered with cloud. Since this has important consequences, especially for the radiative cloud effects, almost all cloud parameterizations describe the fractional coverage of a model grid box with cloud as one of their key parameters. Since cloud fraction is such a fundamental concept that is used in many different ways across

a whole variety of cloud parameterizations, it seems worthwhile to highlight the general implications of the concept of fractional cloud cover.

Assuming that clouds form whenever the specific humidity locally exceeds its saturation value, which occurs if sufficient cloud condensation nuclei (CCN) are available (see below), fractional cloud cover implies that certain parts of a model grid box become supersaturated before others. This has several implications. One of them is that clouds exist in the model grid box before the grid-mean relative humidity reaches the saturation value of 100%. This has been used in many cloud parameterizations to determine the cloud fraction by defining a critical relative humidity, RH_{crit} , above which clouds exist in a grid box and a functional relationship that increases cloud cover from zero below RH_{crit} to one when the entire grid box is saturated. It should be obvious that the definitions of both RH_{crit} and the functional relationship are far from unique and for many years cloud parameterization was nothing more than attempting to find and refine such definitions.

Another consequence of considering cloud fraction is that there must exist a distribution of humidity and temperature around their mean value in a grid box. The knowledge of these variations would in fact be sufficient to describe the cloud field within a grid box. Figure 1 provides an illustration of this idea using the concept of total water q_t , which is the sum of the humidity q and condensate amount q_l . In a one-dimensional model grid box, both the total water q_t and the saturation humidity q_s (dependent only on temperature and pressure) are assumed to be nonuniform. In those areas where the humidity exceeds the saturation value ($q_t > q_s$), clouds are assumed to exist and the sum of the cloud areas (c) divided by the size of the grid box (x) is the total cloud fraction, a , where $a = c/x$. The mathematical technique used to describe these variations describes joint probability distribution functions (PDFs) for a temperature variable and a humidity variable. Unfortunately, the distribution functions are neither known well enough nor expected to be unique and will depend on many different physical processes. Nevertheless, the introduction of the idea of

Figure 1 Schematic of the existence of clouds in the supersaturated areas of a one-dimensional model grid box. The x -axis represents space. The solid line (q_t) shows the value of total water as a function of location within the grid box. The dashed line (q_s) shows the saturation value of specific humidity. Areas in which $q_t > q_s$ represent clouds, indicated by the hatched areas. The total cloud fraction, c , is equal to sum of the cloudy areas a_1 , a_2 , and a_3 .

distributions provides a conceptual framework for the development of cloud parameterizations.

As well as the representation of subgrid heterogeneity, a cloud parameterization can also represent the microphysical processes that describe phase changes and precipitation formation. The degree of complexity depends very much on the computational power available, the application, and our knowledge of the microphysical processes themselves. One of the microphysical processes to be described in any cloud parameterization is the condensation process. This theoretically involves the description of two distinct processes: the nucleation of cloud particles and their initial growth by diffusion of water vapor toward the nucleated particles. It is well known that the main warm-phase nucleation process in the atmosphere is that of heterogeneous nucleation of cloud water droplets on small aerosol particles, usually referred to as CCN (see **Aerosols: Aerosol–Cloud Interactions and Their Radiative Forcing; Clouds and Fog: Cloud Microphysics**). In the presence of abundant CCN in the atmosphere, condensation occurs whenever the relative humidity with respect to water exceeds its saturation value by often less than 1%, while in the absence of CCN large values of supersaturation (several hundred percent) are needed to allow homogeneous nucleation of sufficiently large droplets. In order to avoid the complex treatment of nucleation processes, most cloud parameterizations to date assume that CCN are always available in sufficient numbers and the condensation problem reduces to converting any supersaturation directly to cloud water. For ice particles, nucleation in the atmosphere can occur via heterogeneous or homogenous nucleation. Supersaturations with respect to ice are frequently observed in the upper troposphere, complicating the parameterization of ice clouds. Many other microphysical processes may also be represented in cloud parameterizations with varying degrees of complexity, such as the conversion of cloud to precipitation (autoconversion, accretion, aggregation), evaporation and melting, but these are discussed elsewhere (see **Clouds and Fog: Cloud Microphysics**).

Common Approaches to Cloud Parameterization

The previous section has established the reasons why cloud processes need to be parameterized in atmospheric models.

The main effects of clouds were found to be their influence on the radiative fluxes, their latent heat effects, and the ability to transport heat, moisture, and momentum in case of convective clouds. It was also established that all but the radiative effects of convective clouds are treated in a separate convection parameterization, which is not the subject of this article. The role of clouds for atmospheric models was recognized early on, although in the first models it was mainly the latent heat effects that were considered to be important. This section gives a brief overview of the major steps in the history of cloud parameterization. Various approaches are considered in the context of the major effects that need to be described in models. Each of the periods of development in cloud parameterization can be assessed using the following four questions.

1. How are nonconvective condensation processes on subgrid scales described?
2. How are the radiation effects of the clouds derived after answering (1)?
3. How are the convection and cloud parameterizations linked?
4. How are the microphysical processes that lead to precipitation generation described?

Table 1 provides an overview over the timeline of key aspects of the treatment of cloud-related processes in atmospheric models.

Early Condensation Schemes

In the development of early GCMs in the 1960s, the latent heat effects of both convective and nonconvective condensation processes needed to be considered. Furthermore, since models included an evolution equation for a humidity variable, unphysical states of supersaturation needed to be avoided in the evolution of the model variables. Therefore, a simple but effective condensation scheme was introduced into the models. Its basic idea was to readjust back to saturation any possible supersaturated states occurring on the grid scale at the end of a model time step. The condensate thus formed was removed instantaneously as precipitation. Hence, although condensation processes and therefore their latent heat effects were described, it was not clouds but precipitation that was formed during the condensation. A similarly simple description of

Table 1 An overview of the historic evolution of key aspects of cloud parameterization. The symbols are defined as follows: $\bar{q}$ is the grid-mean specific humidity; q_s is the grid mean of its saturation value; a represents cloud fraction with a_{cu} describing the contribution from convectively generated clouds to that value; l represents the condensate content, with l_{cu} again describing that in convective clouds; RH is the grid-mean relative humidity and CP is the rate of convective precipitation

	Modeling period			
	1960/1970s	1970/1980s	1980/1990s	Now and beyond
Condensation (nonconvective)	$\bar{q} > q_s$	$\bar{q} > q_s$	l prognostic function of outcome of processes	l prognostic function of the processes themselves
Radiation effects	Prescribed zonal mean albedo and emissivity of clouds	$a = f(\text{RH})$ l prescribed	$a = f(\text{RH})$ l prescribed	a prognostic l prognostic
Convection	No cloud interaction	$a_{cu} = f(\text{CP})$ l_{cu} prescribed	$a_{cu} = f(\text{CP})$ l_{cu} prescribed	Condensate and mass as sources for a and l
Microphysics	None	None	Simple bulk microphysics	Complex bulk microphysics

convection was used in which the temperature lapse rate for saturated grid columns was not allowed to exceed that of a moist adiabat. Any condensate formed in this 'moist convective adjustment' process was also removed as precipitation. The role that radiation effects of clouds play in the general circulation was considered small, so that most early GCMs used prescribed zonally averaged cloud albedos and emissivities as input for their radiation calculations. Since all condensate was removed as precipitation, no description of microphysical processes was necessary; hence, early GCMs described only condensation processes with no cloud interaction whatsoever. In fact one could argue from today's point of view that early GCMs did not parameterize clouds but precipitation. The first column in [Table 1](#) represents this period in the evolution of cloud parameterization.

Diagnostic Cloud Schemes

It was soon recognized that the radiative effects of clouds might play a crucial role in the general circulation of the atmosphere. The next generation of cloud parameterizations was therefore aimed at providing some interaction of cloudiness and the other model variables. This was usually achieved by parameterizing the cloud fraction as a function of relative humidity. This type of parameterization had already been proposed for early models but it was not used in GCMs until the 1980s. The reasons for this are not entirely obvious, but the difficulties of validating the model predictions of cloud fraction and the rather limited computing power available at the time were factors.

Relative humidity schemes rely on the concept that if the grid-mean relative humidity exceeds a threshold value RH_{crit} , usually on the order of 80%, it is likely that some part of the grid volume has already reached saturation and therefore clouds start to form. If the grid-mean relative humidity reaches 100%, the entire grid box is assumed to be covered with clouds. Since all models using this approach still used the description of condensation as before, the radiative and latent heat effects of clouds were entirely decoupled. Furthermore, since condensation occurred only for grid-mean values of relative humidity above 100% but clouds existed before that, the amount of condensate needed for the description of the radiative effects of the model clouds was simply prescribed.

The development of more complex convection parameterizations allowed convectively generated clouds to be described as a function of the results of the convection parameterization. This was often achieved by linking the cloud fraction to the precipitation produced in the convection scheme and again prescribing the condensate content. The simple removal as precipitation of any moisture in excess of the saturation humidity makes the description of microphysical processes unnecessary.

This type of cloud parameterization is usually referred to as the 'diagnostic' approach, since the main cloud parameters (cloud fraction and condensate amount) are diagnosed using the grid-averaged quantities, and is represented by the second column in [Table 1](#). Over the years, the basic relative humidity approach was developed, by introducing additional predictors such as vertical motion and inversion strength at the top of convective boundary layers, into the cloud fraction description.

It is noteworthy that this approach provides reasonable estimates of many of the main observed cloud patterns and can be made to work well by adjusting the many free parameters in the parameterization. This, together with a low computational cost, made it a widely used parameterization approach right up to the mid-1990s.

Prognostic Condensate

One of the major drawbacks of the diagnostic approach described above is the obvious disconnection of the cloud latent heat effects from the radiative effects. Sundqvist introduced an additional prognostic model equation for cloud condensate, previously only applied in cloud-scale modeling, establishing this link for a GCM parameterization. By explicitly predicting the amount of condensate formed, a link to the radiative impact of the clouds could be created through the direct use of the predicted condensate in the radiation calculations. A consistent diagnostic treatment of cloud fraction was also introduced in which the cloud fraction remains a function of the grid-mean relative humidity, which is now directly influenced by the condensation processes that are allowed to occur before grid-mean saturation is reached.

The description of convective clouds remained unaltered by Sundqvist's approach. One immediate consequence that should play a major role in the further development of cloud parameterizations is that the conversion of some of the cloud condensate to precipitation needs to be described. Very simple descriptions of the autoconversion process together with some intuitive parameterization of the precipitation-enhancing collection and Bergeron-Findeisen mechanism were used. Although simple, the use of a parameterization scheme of this kind for the first time acknowledged the need to describe microphysical processes as part of the cloud parameterization problem.

Statistical Schemes

In parallel to the introduction of what is now usually known as 'the Sundqvist parameterization,' another approach emerged, based on ideas originally applied in much higher-resolution cloud models. Here, the parameterization of clouds is based on the idea outlined above that the existence of clouds on a subgrid scale requires that the humidity and its saturation value be somehow distributed around their grid-mean values. The knowledge of their PDFs is therefore sufficient to describe both cloud fraction and condensate content within a grid box. The most common use of this idea is by means of a joint PDF for a temperature variable and a humidity variable. Since it was originally developed for the description of nonprecipitating boundary layer clouds, conservative thermodynamic variables such as liquid water potential temperature and total mixing ratio are often preferred.

[Figure 2](#) illustrates the general idea of this approach. Liquid water potential temperature and total mixing ratio are assumed to be distributed with a joint PDF. A saturation curve for a given grid-mean temperature and pressure is then drawn. All the values of the PDF that lie above this saturation curve represent clouds and the cloud fraction and condensate content can be calculated by integrating over this part of the distribution.

Figure 2 Schematic diagram of a possible distribution of liquid water potential temperature, Θ_l ; and total water, q_l ; in a model grid box and its implication for clouds.

The crucial question for a successful application in GCMs is the definition of the distribution function itself. Different approaches were taken here using either fully prescribed and fixed PDFs or simple links of some of the distribution parameters (e.g., variance) to the turbulence parameterization. A critical issue for the use of the PDF of variables is that their conservation breaks down in the presence of precipitation, which needs to be addressed for implementation in a GCM.

Since it is obvious that cloud fraction and cloud condensate content within a grid box do depend on PDFs as used in the parameterization, this approach for parameterization appears promising if the evolution of the PDF can be predicted from the evolution of the resolved scales. Note that since the result of a PDF-based parameterization is a condensate content and a cloud fraction, there is a similar requirement as for the Sundqvist scheme to describe the microphysical processes for the conversion of cloud to precipitation.

Fully Prognostic Schemes

In the early 1990s a new approach to cloud parameterization emerged, in which both the time evolution of the cloud condensate and that of cloud fraction are described using prognostic equations,

$$\frac{\partial l}{\partial t} = A(l) + S(l) - D(l) \quad [1a]$$

$$\frac{\partial a}{\partial t} = A(a) + S(a) - D(a) \quad [1b]$$

In eqns [1a] and [1b], l is the grid-mean condensate content and a is the cloud fraction. $A(l, a)$ represents the advection of the two variables, $S(l, a)$ represents any sources of condensate or cloud fraction, and $D(l, a)$ represents their dissipation. This approach was pioneered by Tiedtke and has been introduced into a number of GCMs.

More recently, research has been focusing on combining the fully prognostic approach with that used in statistical schemes. Here, instead of predicting grid-mean condensate and cloud fraction, the moments of a probability density function (mean, variance, skewness) are used as prognostic model variables and

the relevant cloud parameters are deduced from the PDF as in the traditional statistical cloud parameterizations.

Contemporary Issues

Convectively Generated Clouds

Both the introduction of a prognostic variable for the description of cloud condensate and the use of a PDF condensation scheme solve the problem of linking the latent heat effects of clouds with the macroscopic parameters entering the radiation calculations. A major remaining problem in both approaches is that they do not include clouds produced by convective processes as an integral part of their formulation. In models using either of these two cloud parameterization approaches, convective clouds are usually still treated as they were in diagnostic cloud parameterizations.

A variety of approaches for tackling this problem have been devised since then. The most common approach used in the schemes solving a prognostic equation for the condensate is to treat water substance detrained from convective updrafts as a source of liquid water for the 'stratiform' clouds. The exact nature of the link depends on the definition of 'detrainment' and can vary for different schemes. Although using 'detrained' condensate from convection as a source for cloud condensate has become a standard way of linking convection and radiation through cloud formation, the variety of different ad hoc techniques used points to a lack of understanding of how exactly this link should be represented. A further major problem is how to represent the cloud fraction resulting from the detrainment process. Recent parameterizations have attempted to derive consistent treatments of both condensate and cloud fraction from convection. Despite the progress made in this area, the inclusion of clouds generated by convective processes remains an uncertain area of active research.

Process-Oriented Approaches

More and more contemporary cloud parameterizations have moved from what can be described as an integrating approach to a process-oriented treatment of clouds. The difference between the two approaches is illustrated in Figure 3. Figure 3(a) summarizes the concept of integrating cloud parameterizations. Various physical processes, such as resolved scale ascent, convection, turbulence, etc. modify one or several resolved variables and/or their tendency. Those resolved quantities (e.g., relative humidity or its tendency) are then used to evaluate the evolution of the model clouds. A major drawback of this approach is that the effects of parameterized processes, such as convection, that contribute directly to cloud formation and dissipation are first 'integrated' onto the grid scale only to be reinterpreted for subgrid-scale cloud processes.

In contrast, in a process-oriented approach (Figure 3(b)) each potentially cloud-modifying process, resolved (e.g., large-scale ascent) or parameterized (e.g., convection) directly alters the model's cloud variables as well as other resolved-scale model variables. In this way, information available at the level of other physical parameterizations can be directly used in the cloud scheme and the clouds become a more integral part of the parameterization package. The physically more

Figure 3 Schematic of the different approaches to cloud parameterization: (a) the principles of ‘integrating’ cloud schemes; (b) the process-oriented approach. Note that arrows indicating the obvious direct interactions between individual processes other than cloud processes have been omitted for clarity.

appealing process-oriented approach to cloud parameterization significantly raises the level of complexity of the parameterization, since the influence that each physical process exerts on the model clouds needs to be explicitly described.

Cloud Microphysics, Subgrid Heterogeneity, and Model Resolution

Most recently, the attention in cloud parameterization has shifted significantly toward the treatment of cloud microphysics. This has been facilitated by increased computing power and the availability of sophisticated microphysics parameterizations from cloud-resolving and mesoscale numerical models. Although increased sophistication in describing cloud and precipitation processes in GCMs is certainly justified, the transplantation of a microphysics scheme from a cloud-resolving model to a GCM is not without problems. This is mainly due to the scales at which the forcing terms (input variables) for the microphysical scheme are available and to the difference in time steps used by the different models. Microphysical processes are highly nonlinear and their parameterization has to rely on the knowledge of the local amount of condensate. In GCMs often only the grid-mean value (or cloud-mean value if cloud fraction is a model variable) for condensate is known, which results in modifications of microphysical constants in order to achieve reasonable cloud condensate and precipitation amounts. The desire to improve on this is leading to increasing emphasis on the representation of subgrid heterogeneity for a more realistic description of the microphysical interactions at scales smaller than the grid scale.

Another trend is the continuing increase in resolution of GCMs. With higher horizontal and vertical resolution, the

concept of cloud fraction actually becomes less important, the forcing becomes better resolved (e.g., updraft strength), and grid-point values of cloud condensate become more representative of local conditions. Hence, as resolution increases, it is common to put less emphasis on the representation of subgrid cloud heterogeneity and apply more complex and physically more realistic parameterizations of cloud microphysics. However, a single GCM can be used with widely varying model resolutions for different applications and there is therefore a continuing requirement for cloud parameterizations with a realistic treatment of both subgrid heterogeneity and microphysics that work effectively and efficiently across a wide range of scales.

Representing the Ice-Phase, Mixed-Phase, and Cloud–Aerosol Interactions

There are still many uncertainties in our knowledge of cloud and precipitation processes and how to represent these in atmospheric models. Ice-phase microphysics is particularly complex due to the number of ways in which ice particles can nucleate and the widely varying particle shapes (habits) observed in the atmosphere. Improving the representation of microphysical processes in the ice-phase, as well as their interactions with supercooled liquid water in the mixed-phase, is an ongoing challenge. There is an increased interest in aerosol–cloud–radiation interactions, particularly in the context of climate change, and although there remains many uncertainties, there is active research to improve our understanding of cloud–aerosol interactions and their representation in atmospheric models.

Evaluating with Observations

In recent years there has been an increase in the number of high quality observations of cloud and precipitation, particularly from remote sensing radar and lidar both at fixed locations on the ground and globally from satellite. These observations are providing a wealth of information on the distribution of cloud and precipitation and their variability in space and time, and an unprecedented opportunity to evaluate models, increase our understanding and improve the parameterization of cloud and precipitation.

Nomenclature

$\hat{c}$ Intrinsic phase speed.

ϵ Intermittency.

f Coriolis parameter.

F Vertical flux of horizontal momentum.

F_s Saturated momentum flux magnitude.

Fr Froude number.

H Density scale height.

h_0 Orographic height parameter.

J/c_p Thermal forcing.

$\hat{k}$ Unit vector in the vertical.

K_{zz} Vertical diffusion coefficient.

(k, m) (Horizontal, vertical) wave numbers.

λ_z Vertical wavelength.

N Buoyancy frequency.

$\hat{\omega}$ Intrinsic frequency.

Φ Geopotential.

Pr Prandtl number.

ρ Density.

σ_h Subgrid scale topography standard deviation.

R Gas constant.

t Time.

T Temperature.

$\bar{u}$ Wind in the direction of wave propagation.

V Horizontal wind vector.

ω Vertical wind.

X Momentum forcing.

z Vertical distance.

Synopsis

Gravity waves can carry momentum and energy fluxes vertically across deep regions of the atmosphere ranging from the surface to the thermosphere. Dissipation of these fluxes can lead to net changes in the momentum and energy budgets of the surrounding fluid. These processes are important to global circulation, and parameterization approaches for global circulation models are summarized. Constraining information from observations is also briefly summarized along with outstanding issues and recent developments.

Introduction

Gravity waves are oscillations that cause perturbations in the winds, temperature, density, and pressure fields in the atmosphere. They are also called buoyancy waves (*see Gravity Waves: Buoyancy and Buoyancy Waves: Theory*) because the restoring force for their oscillation is the buoyancy force associated with vertical parcel displacements in a stably stratified fluid. Because the density of the atmosphere decreases exponentially with height, vertically propagating gravity waves have amplitudes that tend to grow exponentially with height in the absence of dissipation. Therefore, even small-amplitude waves in the lower atmosphere may have very large effects at high altitudes. Gravity waves carry momentum and energy fluxes, so their dissipation can lead to net changes in the momentum and energy budgets of the surrounding fluid.

The effects of dissipation of gravity wave momentum fluxes on the larger-scale circulation must be parameterized in global models because the resolution required to model them directly is prohibitively fine for most weather forecasting and climate applications. The waves important to the circulation in the atmosphere have horizontal wavelengths ranging from about ten to thousands of kilometers. The largest of these can be resolved in today's global models. However, the vertical wavelength of a gravity wave will vary substantially with height

owing to the effects of wind shear, and it is important to represent vertical wavelengths as small as 1 km. Gravity waves with periods as short as 5–10 min can carry significant momentum flux vertically. Further, the sources of these waves include processes that are also parameterized and/or poorly resolved, namely, convective heating, fine-scale topography, imbalance in the jet stream, and frontal structures. Direct modeling of the spectrum of gravity waves in global models is therefore still not feasible at the present time.

Parameterization of Gravity Wave Effects

Parameterization of gravity waves generated by flow over fine-scale topography is now widely used in atmospheric climate and weather forecasting models. When the effects of these waves were introduced in climate models, they significantly reduced an eastward wind bias in the Northern Hemisphere winter troposphere and lower stratosphere that had previously tended to grow worse with improved resolution. The parameterized orographic gravity wave drag provided a realistic dissipation process that transported momentum from the surface to the free atmosphere.

Global models of the atmosphere that include many levels above the tropopause also require parameterization of gravity

waves from other sources. Parameterized orographic waves are characterized by phase speed $c = 0$ relative to the ground (stationary waves), while waves from other sources may have wide-ranging phase speeds (nonstationary waves). The detailed characteristics of the nonstationary waves are not well understood. Parameterizations of these tend to assume a simple latitudinally and/or seasonally varying source spectrum of wave phase speeds. The effects of these waves are most pronounced in the mesosphere, where the drag they exert on the middle atmosphere jets drives a strong summer-to-winter meridional circulation that reverses the temperature gradient that would be predicted from consideration of solar heating alone. In the stratosphere, gravity wave forcing also drives a mean meridional circulation, though the contribution of gravity waves is secondary to the planetary wave forcing. Dissipation of gravity wave energy fluxes causes important vertical mixing of heat and constituents in the upper mesosphere and lower thermosphere, and this is a very important process in the oceans.

The parameterization of gravity wave effects has therefore focused on estimation of two terms for inclusion in the fundamental fluid equations solved in global models.

- A body forcing term $\mathbf{X}$ for the momentum equation, e.g., eqn [1].

$$\frac{D\mathbf{V}}{Dt} = -f\mathbf{k} \times \mathbf{V} - \nabla\Phi + \mathbf{X} \quad [1]$$

Here $\mathbf{V}$ is the vector wind, f is the Coriolis parameter, $\mathbf{k}$ is the unit vector in the vertical, and Φ is the geopotential (see **Dynamical Meteorology: Overview** for additional discussion). The meaning of eqn [1] is that the acceleration of a fluid parcel $D\mathbf{V}/Dt$ is equal to the sum of forces per unit mass. The three forces shown here are the Coriolis force ($-f\mathbf{k} \times \mathbf{V}$), the pressure gradient force ($-\nabla\Phi$), and the wave-driven force $\mathbf{X}$.

- An ‘eddy diffusion coefficient’ K_{zz} for describing vertical mixing effects on temperature and trace constituents in the thermodynamic equation and in equations describing tracer transport, e.g., eqn [2].

$$\frac{DT}{Dt} + \frac{wN^2H}{R} = \frac{J}{c_p} + \frac{1}{\rho} \frac{\partial}{\partial z} \left[\rho K_{zz} \left(\frac{\partial T}{\partial z} + \frac{g}{c_p} \right) \right] \quad [2]$$

This is the thermodynamic energy equation including a diffusive mixing term due to unresolved gravity waves. T is the temperature, w is the vertical velocity, N is the buoyancy frequency, H is the scale height, R is the gas constant, and J/c_p defines the thermal forcing (again see **Dynamical Meteorology: Overview**). Gravity wave mixing effects are considered only in the vertical because the atmosphere is generally treated as horizontally homogeneous over the scale of the unresolved waves. A similar mixing term can be applied to conservation equations for trace constituents.

The eddy diffusion term is only known to be important at mesospheric and lower thermospheric altitudes, while the momentum forcing term is important at levels ranging from the upper troposphere to the lower thermosphere. Momentum diffusion and direct heating terms can also arise from gravity wave dissipation, but these have been neglected in most parameterization applications. However, the heating term is

now believed to be important locally in the mesosphere energy budget (see **Gravity Waves: Overview** for additional discussion of the physics of these effects and their importance in the atmosphere).

Simplifying Assumptions

Parameterizations in global models assume that wave propagation is one dimensional and purely vertical. Effects of the Coriolis force on waves with the lowest intrinsic frequencies are also usually neglected ($\hat{\omega}^2 \gg f^2$, where $\hat{\omega}$ is the wave intrinsic frequency). The hydrostatic approximation is also generally made, which assumes that the horizontal wavelength is much longer than the vertical wavelength, or $\hat{\omega}^2 \ll N^2$. With these assumptions, momentum forcing is proportional to the vertical gradient of the vertical flux of horizontal momentum (or Reynolds stress) $\mathbf{F} = \rho(\overline{u'w'}, \overline{v'w'})$ carried by the wave and eqn [3] applies,

$$\mathbf{X} = -\frac{1}{\rho} \frac{\partial \mathbf{F}}{\partial z} \quad [3]$$

The parameterization problem then reduces to (1) specifying the gravity wave flux $\mathbf{F}_0$ at some initial height z_0 usually taken to be the source altitude somewhere in the troposphere or near the tropopause, then (2) computing the dissipation as a function of height or $\mathbf{F}(z)$. Dissipation could be due to any number of effects including radiative damping, nonlinear wave-wave interactions, wave breaking due to convective or dynamical instability, and molecular diffusion. Different parameterizations make different assumptions about which dissipation processes are important, but for calculating of the momentum forcing term $\mathbf{X}$, only the net effect of these processes on $\mathbf{F}(z)$ is important. Figure 1 shows a schematic profile of momentum flux for a wave carrying positive momentum flux dissipating as a function of height. This dissipation via eqn [3] results in a positive force. The direction of the force will always be such as to accelerate or ‘drag’ the background wind speed toward the wave intrinsic phase speed.

Figure 1 An example vertical profile of momentum flux $\mathbf{F}$ and the force $\mathbf{X}$ resulting from the dissipation of a wave with initial positive momentum flux (and positive intrinsic phase speed) as a function of height.

When waves break down, mixing is likely, and the eddy diffusion term can be important. High-resolution numerical model studies have also shown that the specific characteristics of the wave at the point of breaking or the nature of the instability process may strongly affect the degree of mixing. This makes the relationship between the momentum forcing and the vertical diffusion uncertain. Given the changes observed in gravity waves with height described in article **Gravity Waves: Overview**, the relationship between X and K_{zz} may even vary dramatically with height between the tropopause and the upper atmosphere.

Lindzen-Type Parameterizations

The most commonly applied parameterizations are based on a formulation by Richard Lindzen, first outlined in 1981, and these are generally referred to as ‘Lindzen’ or ‘Lindzen-type’ parameterizations. These treat the spectrum of gravity waves as a discrete set of simple plane waves varying only in their phase speeds c and propagation directions. Each wave mode is assigned an amplitude at a specified source level z_0 . As the waves propagate vertically, they are Doppler shifted and refracted by vertical variations in the background wind. Doppler shifting is described by the change in the intrinsic phase speed $\hat{c}(z)$ or frequency $\hat{\omega}(z)$ associated with vertical shear in the component of horizontal wind in the direction of the wave propagation $\bar{u}$ (eqn [4]). k is the horizontal wave number.

$$\hat{c}(z) = \frac{\hat{\omega}(z)}{k} = c - \bar{u}(z) \quad [4]$$

Refraction describes the corresponding change in vertical wave number m with height (eqn [5]).

$$m(z) = \frac{N(z)k}{\hat{\omega}(z)} \quad [5]$$

Refraction also occurs with changes in N . When the wave amplitude exceeds the threshold for convective instability (see **Gravity Waves: Overview**), the wave amplitude is assumed to saturate at that threshold value and grow no further. This assumption gives an estimate of wave dissipation as a function of height. In terms of the momentum flux, the saturation limit can be written as eqn [6].

$$|F| \leq F_s = \text{Fr}^2 \frac{\rho k}{2N} |c - \bar{u}|^3 \quad [6]$$

Here, F_s is the saturated value of the momentum flux and Fr is the critical Froude number (generally assumed ~ 1). Applying eqn [3] then gives the momentum force in the saturated region (eqn [7]).

$$X = \varepsilon \frac{k(c - \bar{u})^3}{2N} \left(\frac{1}{H} + \frac{3d\bar{u}/dz}{c - \bar{u}} \right) \quad [7]$$

Vertical gradients in N have been neglected, and the shear term is also sometimes neglected. The factor ε has been described as an efficiency factor or intermittency. For parameterization of nonzero phase speed waves, the sources are generally specified to be globally uniform, or varying in simple ways, because we lack better knowledge of the detail of how to treat these waves. The factor ε then is meant to describe the

fractional coverage of waves and wave sources in space and time. It is applied only in the force eqn [7] and not to the flux and saturation condition eqn [6] because the local amplitudes of the waves should determine the breaking levels and saturation regions. If ε is small, the spatially and temporally averaged amplitudes of gravity waves will be much smaller than the local amplitudes.

A vertical diffusion coefficient, derived by assuming the wave dissipation described by eqn [6] occurs because local mixing effects maintain the local temperature gradient at the adiabatic temperature lapse rate (the limit for convective instability). This assumption gives eqn [8].

$$K_{zz} = \frac{1}{\text{Pr}} \frac{(c - \bar{u})X}{N^2} \quad [8]$$

Note that in eqn [8] the uncertain Prandtl number (Pr) has been included explicitly. This factor describes the ratio of thermal to momentum diffusion and has been assigned values ranging from 1 to 10 in model applications. While the force X always has the same sign as the intrinsic phase speed $\hat{c} = c - \bar{u}$, the vertical diffusion coefficient is always positive.

Orographic Wave Parameterization

For orographic wave drag parameterizations, the wave phase speed is set to $c = 0$, which simplifies eqns [6]–[8] to eqns [9]–[11].

$$|F| \leq F_s = \varepsilon \text{Fr}^2 \frac{k}{2N} |\bar{u}|^3 \quad [9]$$

$$X = \varepsilon \frac{k\bar{u}^3}{2N} \left(\frac{1}{H} - \frac{3}{\bar{u}} \frac{d\bar{u}}{dz} \right) \quad [10]$$

$$K_{zz} = -\frac{1}{\text{Pr}} \frac{\bar{u}X}{N^2} \quad [11]$$

The efficiency factor ε is applied not only to the force eqn [10] but also to the local fluxes eqn [9] because here ε describes processes that limit wave amplitudes at the source, such as flow blocking. The spatial and temporal intermittency is also explicit in the source description since waves are only generated over topography and their amplitudes will depend on the background wind speed.

Many variants exist for how to specify the topographic source flux F_0 , but one of the simplest that is still commonly applied in global models assumes the source is a function of the topographic height standard deviation σ_h of subgrid scale topography within a model grid box, e.g., eqn [12], where the subscripts refer to values at the source level close to the surface.

$$F_0 = -\frac{\varepsilon k}{2} \rho_0 N_0 V_0 h_0^2 \quad [12]$$

The amplitude $h_0 = \min(2\sigma_h, \text{Fr}V_0/N_0)$, where the Froude number limit crudely accounts for blocking effects.

Spectral Parameterizations

Parameterization methods for describing a full spectrum of gravity wave effects are now in use, and are an essential

component of chemistry–climate models. Spectral parameterizations are intended to describe waves generated by a collection of sources, and are generally applied together with an orographic wave drag scheme. With discrete parameterizations like the Lindzen-type scheme with only a few wave phase speeds specified, the drag effects on the mean flow can be very sudden or discrete in time and in the horizontal plane because of the dependence of the breaking criteria (eqn [6] or [9]) on $(c - \bar{u})$. The spectral parameterizations can provide smoother gravity wave effects for incorporation in global models seeking to describe the climatological effects of gravity waves on the mean flow.

The mechanism proposed to describe wave dissipation as a function of height varies among the different spectral parameterizations, and each also has restrictions on the properties of the wave spectrum that can be specified at the source level. The current uncertainty that exists in how to specify the gravity waves at their sources is large enough that it remains

difficult to separate source differences in these models from differences in the description of wave dissipation. Figures 2 and 3 serve to illustrate this problem.

Figure 2(a) shows normalized energy spectra that differ only in the shape of the spectrum at long vertical wavelengths $25 \text{ km} \geq \lambda_z \geq 2.5 \text{ km}$. Long vertical wavelength waves $>10 \text{ km}$ are more difficult to observe in the lower stratosphere near gravity wave sources. The three spectra in Figure 2(a) are meant to describe the range of uncertainty in the long-wavelength portion of the spectrum. Figure 2(b) shows the three corresponding momentum flux spectra as a function of intrinsic phase speed $\hat{c}$, where it has been assumed that the waves propagate in the zonal direction and the spectrum is symmetric. The uncertainty in long vertical wavelength waves translates to an uncertainty in waves with high intrinsic phase speeds. The conversion from energy to momentum flux requires knowledge of the intrinsic frequency, which is also difficult to determine from observations, adding additional

Figure 2 Gravity wave spectra for (a) energy as a function of vertical wave number m and (b) momentum flux per unit density as a function of intrinsic phase speed $\hat{c}$. The dashed, solid, and dash-dotted lines in each panel represent spectra that vary at low wave numbers as m^2 , m^1 , and m^0 , respectively.

Figure 3 Vertical profiles of (a) zonal wind input into the parameterized momentum force calculation and (b) the three force profiles that result from the three different momentum flux spectra in Figure 2(b). To derive the force, a horizontal wavelength of 200 km was assumed, and the efficiency factors for each spectrum were chosen so that the integrated momentum flux in each spectrum was the same (equal eastward and westward fluxes of 0.001 Pa).

uncertainty. The three curves have been chosen to illustrate cases with different dependences on high and low intrinsic phase speed waves.

Results of these spectra input to a gravity wave parameterization calculation of the momentum forcing are shown in Figure 3. The integrated momentum flux input is specified to be a constant among the three cases and the source altitude is set at 5 km. The parameterization employed is similar to the Lindzen-type parameterizations, but the spectrum is broken into small increments $\Delta\hat{c} = 1 \text{ m s}^{-1}$, and instead of employing the saturation condition eqn [6] to describe the dissipation as a function of height, each spectral element loses all of its momentum flux at the breaking level.

Figure 3(a) shows the zonal wind profile assumed, and the three zonal force profiles corresponding to the three phase speed spectra are shown in Figure 3(b). The peaks between 60 and 90 km are most sensitive to the large negative intrinsic phase speed portion of the spectrum that has been so difficult to quantify with observations. These differences arise primarily because of the uncertainty in our understanding of this high phase speed portion of the gravity wave spectrum in nature.

Constraints on Gravity Wave Momentum Fluxes

Existing constraints on gravity wave momentum fluxes and forces on the mean flow used to constrain gravity wave drag parameterizations are reviewed here. Every measurement is limited to observing a specific range of gravity wave properties, while other possible waves in the spectrum will not be visible. This leads to the expectation that each observational constraint may be low biased to some extent.

Measurements Local to Sources

Observations of gravity waves just above a localized known source can provide some constraints for parameterizations. Relatively few observations, however, are useful for deriving momentum fluxes. Fewer still can also specify the wave phase speeds, horizontal wave numbers, and propagation directions required to accurately predict their effects on the atmosphere at higher levels. A still smaller number has the capacity to provide the sort of general information needed to parameterize gravity wave sources and how they vary in changing conditions geographically and seasonally.

Observation of gravity waves by radar and aircraft in the lower stratosphere has provided gravity wave momentum fluxes above topographic and convective sources. (Observations have generally been reported as horizontal and vertical wind covariances in units of $\text{m}^2 \text{s}^{-2}$. Those reported here are in $\text{Pa} = \text{kg m}^{-1} \text{s}^{-2}$, which have been multiplied by density ρ . This allows easier comparison of observations at different altitudes because in the absence of dissipation, wind covariances will grow exponentially with height in proportion to ρ^{-1} .) Observations from satellite platforms have also provided some information on gravity wave momentum fluxes to date. These have shown local momentum fluxes. When wave activity was observed over topography of approximately $0.02\text{--}1 \text{ Pa}$. Orographic waves are not always observed to be stationary, but

generally have slow phase speeds and very low frequencies relative to the ground. Model studies have shown that time-varying winds and nonlinear effects can lead to the generation of orographic waves with nonzero phase speeds. Horizontal wavelengths of orographic waves should be related to the scales of surface roughness. Scales observed with relevance to parameterization of circulation effects range from approximately ten to hundreds of kilometers.

Waves observed over deep convective clouds have been reported with momentum fluxes approximately $0.01\text{--}0.2 \text{ Pa}$. Short horizontal wavelengths approximately $10\text{--}100 \text{ km}$ have been observed by aircraft. From satellite measurements, waves from convection have been inferred by proximity to deep clouds and by characteristic concentric ring-shaped patterns. These have shown wavelengths ranging from a few tens to hundreds of kilometers. Longer horizontal wavelengths approximately 500 to several thousand kilometers have been inferred from balloon soundings at tropical locations where convection is the likely source. These are low frequency inertia-gravity waves, and although their horizontal scales are resolvable in most global models, their vertical wavelengths are often too short, and their sources are still poorly represented. Phase speeds for convectively generated waves have also been reported to vary greatly from near zero to approximately 50 m s^{-1} , although the uncertainty in phase speed estimates can be large.

Estimates of mean flow forcing derived from observations of momentum flux remain too uncertain to provide meaningful constraints. However, given the strength of localized fluxes observed and some reasonable assumptions, it is likely that localized forces $\mathbf{X}$ occur at times in the mesosphere with magnitudes of at least hundreds of meters per second per day.

Fluxes and properties of waves appearing above regions of imbalance in the jet stream have been inferred from a few case studies, but no generalization of their properties can yet be described. Model studies suggest that a wide range of horizontal scales are emitted from this source, but phase speeds relative to the ground tend to be small, a few meters per second, being tied to the motion of the underlying synoptic systems. Although aircraft measurements have been used to identify enhanced variance above frontal sources due to waves with scales less than $\sim 200 \text{ km}$, further information on wave properties needed to constrain parameterizations is lacking.

Constraints on Long-Term Average Momentum Fluxes

Longer term averaged gravity wave momentum fluxes provide additional valuable constraints for parameterizations, and together with the local flux constraints above, they illuminate intermittency. Global maps of momentum flux in the lower stratosphere have been computed from satellite measurements and long-duration balloon data that reveal seasonal and geographic patterns. In general, the largest fluxes occur in winter at mid-to-high latitudes. Fluxes near the equator are generally smaller, and a secondary maximum occurs at summer subtropical latitudes. Within these seasonal patterns, localized peaks appear over topography in winter, with monthly- and seasonal-mean peak values of $5\text{--}20 \times 10^{-3} \text{ Pa}$. Away from topography, long-term mean winter fluxes have typical values of approximately $1\text{--}3 \times 10^{-3} \text{ Pa}$. In summer, peaks over

convection are observed with values $\sim 2 \times 10^{-3}$ Pa and background values $< 1 \times 10^{-3}$ Pa. Extremely low values approaching noise limits occur at high summer latitudes poleward of $\sim 60^\circ$.

Although these mean fluxes are at least 10–100 times smaller than localized values, vertical propagation through decreasing atmospheric density and dissipation at high altitudes in the mesosphere and above can lead to large drag forces. Estimates of these forces derived from observations remain too uncertain to provide any meaningful constraints. Global models with self-consistent momentum budget calculations predict forces due to gravity waves of tens of meters per second per day near the mesopause, and in the lower stratosphere due to strong orographic wave forcing, values on the order of $1 \text{ m s}^{-1} \text{ day}^{-1}$.

Recent Developments

Gravity waves generated by flow over orography are parameterized in most global climate and weather forecasting models. Recent developments include more realistic description of the wave properties and momentum fluxes at the source level F_0 , including more realistic descriptions of flow blocking and downstream vortex formation effects, and coupling to surface friction. Recent studies have related some of these changes to the frequency of occurrence of sudden stratospheric warmings in models and to surface climate response patterns. Climate studies have also found that parameterized orographic wave drag responds to long-term changes in zonal winds near the tropopause in a way that leads to acceleration of the stratospheric mean meridional transport circulation.

These results underscore the need for gravity wave parameterizations applied in climate models to respond to long-term changes in climate in realistic ways. All parameterization methods currently respond to changes in zonal wind and stability in the middle atmosphere. In orographic schemes, the source flux F_0 (eqn [12]) also responds to climate changes in near-surface winds and stability. Conversely, most spectral schemes intended to represent other non-orographic gravity waves have sources remain fixed. Some models are now including a variety of different non-orographic gravity wave sources with fluxes that do respond to changes in climate. Such ‘non-orographic source parameterizations’ have been developed for both convective sources and frontal sources and have been applied in a few climate models. These source parameterizations have been based on two-dimensional model studies of convection and frontogenesis. While these convective and frontal source parameterizations represent an advance by allowing the sources to respond in realistic ways to climate changes, the many assumptions made in their application remain unvalidated, leaving large uncertainties in the model responses at present.

Intermittency in the gravity wave fluxes is generally treated with a simple tuning parameter, such as ε in eqn [7]. Intermittency is in reality much more complex: Observed wave amplitudes span at least a factor of 100 with the largest

amplitude waves occurring as extremely rare events. Although in an average sense the momentum fluxes from large- and small-amplitude events may be similar, their effects on the atmosphere will be very different. Large rare events will break at lower altitudes and may force localized responses and/or emit substantial secondary waves, while ubiquitous small events may break at higher altitudes and instead force circulations more similar to the climatological mean effects described in the introduction. New interest in stochastic parameterization methods may open opportunities to include effects of intermittency in more realistic ways in future model applications.

Parameterization of Physical Processes: Turbulence and Mixing

A Beljaars, European Centre for Medium-Range Weather Forecasts, Reading, England

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

The representation of subgrid turbulence in meteorological models for numerical weather prediction and climate is discussed. The following topics are addressed: (1) The importance of turbulence parametrization in large scale models; (2) the choice of conserved variables for mixing in the vertical; (3) the representation of surface fluxes in large scale models; (4) commonly used boundary layer formulations, namely, bulk schemes, local closure, profile formulations, and higher order models; and (5) the cloudy boundary layer.

Introduction

Turbulence is a prominent feature in the atmosphere, particularly in the atmospheric boundary layer. Turbulence length scales vary typically from a few millimeters to a few hundreds of meters, which are smaller than the grid spacing in models of the atmosphere. However, these small-scale motions have a strong impact on the evolution of the mean flow and therefore a parametrization scheme is needed in models that simulate the flow in the atmosphere. A mathematical framework to describe the effect of turbulence on the mean flow can be obtained by separating variables into a mean and a fluctuating part: the so-called Reynolds decomposition. The resulting equations for the mean flow contain variances and covariances of fluctuating quantities that are unknown. This is known as the closure problem. Expressing the unknown quantities in terms of mean flow variables is called turbulence parametrization.

The turbulent transport terms are among the dominant terms in the atmospheric boundary layer equations and govern

the exchange of heat, moisture, and momentum with the surface. In a climate model, it is for instance through the turbulence scheme that the model knows about the sea surface temperature and the heat and moisture input from the surface. Also the momentum sink due to drag at the surface is predominantly controlled by the turbulence parametrization. **Figure 1** shows a latitude height cross section of the mean moisture tendency from turbulent diffusion in a global model. Although turbulence can occur anywhere in the atmosphere (e.g., as clear-air turbulence near the jet stream), the main tendencies are near the surface, illustrating the importance of turbulence for exchange with the surface.

Models of the atmosphere cover a wide range of applications, e.g., canopy flow models, flow over complex topography, air pollution dispersion models, internal boundary layer models, mesoscale models, numerical weather prediction (NWP) models, and climate models. All these models have turbulence schemes to describe the effect of turbulent transport on the mean flow. Dependent on the application, the requirements may vary and it is beyond the scope of this article to cover all options.

Figure 1 North–South vs height cross section of the zonal mean moisture tendencies in the European Centre for Medium-Range Weather Forecasts (ECMWF) numerical weather prediction model. The units are $\text{g kg}^{-1} \text{ day}^{-1}$ with a contour interval of 0.5. Courtesy of Ernst Klinker, ECMWF.

However, most turbulence schemes are built on the same principles. Here we will focus on NWP and climate models.

Turbulence is a very complex and nonlinear flow phenomenon for which no general theory exists. Therefore turbulence schemes rely heavily on insight in the physics of turbulent flow, empirical relations from observations, and on similarity arguments to represent observations. With the increased availability of computer power large eddy simulation models have also become important in providing 'data' to replace or complement observations.

Turbulence can be generated by wind shear or by buoyancy, the latter acting as a strong modulator of the diurnal cycle over land. An atmospheric boundary layer heated from the surface during the daytime is highly turbulent through buoyancy production, whereas the nighttime boundary layer can be very calm through the suppression of turbulence by stable stratification.

Buoyancy generation of turbulence is not always due to heating from the surface. Unstable stratification can also be generated, e.g., by differential advection or by radiative cloud top cooling. Stratocumulus for instance can maintain a well-mixed structure because the cloud top cooling leads to buoyancy-generated turbulence and strong vertical mixing.

Variables

For the description of turbulent transport in the vertical, it is necessary to use thermodynamic variables that are conserved for adiabatic ascent or descent. For the dry case, suitable variables are potential temperature θ or dry static energy s together with specific humidity q (see also Table 1 for the definition of symbols).

Table 1 Symbols and units

Symbols	Description	Units
C_m	Transfer coefficient for momentum	—
C_{mn}	Neutral transfer coefficient for momentum	—
C_h	Transfer coefficient for heat	—
C_{hn}	Neutral transfer coefficient for heat	—
C_q	Transfer coefficient for moisture	—
C_{qn}	Neutral transfer coefficient for moisture	—
C_p	Specific heat at constant pressure	$\text{J kg}^{-1} \text{K}^{-1}$
d/dt	Total derivative $\partial/\partial t + U\partial/\partial x + V\partial/\partial y + W\partial/\partial z$	s^{-1}
E	Turbulence kinetic energy	$\text{m}^2 \text{s}^{-2}$
F_m	Louis momentum stability function of Ri	—
F_h	Louis heat stability function of Ri	—
g	Gravitation constant	m s^{-2}
h	Boundary layer depth	m
k	Von Kármán constant	—
l	Mixing length	m
L	Obukhov length	m
L_v	Latent heat of vaporization of water	J kg^{-1}
p	Pressure	Pa
p_o	Surface pressure	Pa
q	Specific humidity	kg kg^{-1}
q_l	Liquid water/ice content	kg kg^{-1}
q_t	Total water content	kg kg^{-1}
q_{sat}	Saturation specific humidity	kg kg^{-1}
R	Gas constant	$\text{J kg}^{-1} \text{K}^{-1}$

(Continued)

Table 1 Symbols and units—cont'd

Symbols	Description	Units
R_i	Gradient Richardson number	—
R_{ib}	Bulk Richardson number	—
s	Dry static energy	J kg^{-1}
s_l	Liquid water static energy	J kg^{-1}
s_v	Virtual dry static energy	J kg^{-1}
t	Time	s
T	Temperature	K
U	Velocity in x -direction	m s^{-1}
V	Velocity in y -direction	m s^{-1}
W	Velocity in z -direction	m s^{-1}
u_*	Friction velocity	m s^{-1}
w_*	Free convection velocity scale	m s^{-1}
w_e	Entrainment velocity	m s^{-1}
x	Horizontal coordinate	m
y	Horizontal coordinate	m
z	Vertical coordinate	m
z_{om}	Roughness length for momentum	m
z_{oh}	Roughness length for heat	m
z_{oq}	Roughness length for moisture	m
Greek symbols	Description	Units
Δ	Temperature jump at boundary layer top	K
ε	Turbulence dissipation rate	$\text{m}^2 \text{s}^{-3}$
ϕ_m	MO gradient stability function for momentum	—
ϕ_h	MO gradient stability function for heat	—
γ	Lapse rate above boundary layer	K m^{-1}
ψ_m	MO integral stability function for momentum	—
ψ_h	MO integral stability function for heat	—
θ	Potential temperature	K
θ_l	Liquid water potential temperature	K
θ_v	Virtual potential temperature	K
ρ	Density	kg m^{-3}
λ	Asymptotic mixing length	m
ν	Kinematic viscosity	$\text{m}^2 \text{s}^{-1}$
Symbols	Subscripts, superscripts etc. for variable X	
X_l	X -Value at lowest model level	
X_s	X -Value at surface	
X_m	Mixed layer value of X	
X_o	X -Value at the surface (for fluxes)	
X_h	X -Value at boundary layer top	
X'	Fluctuation of X	
$\bar{X}$	Averaged X	
$\vec{X}$	Vector X	

$$\theta = T(p_o/p)^{R/c_p}, \quad [1]$$

$$s = c_p T + gz. \quad [2]$$

In these expressions, T represents the temperature, p is the pressure, p_o is the reference pressure (usually 1000 hPa), R is the gas constant, c_p is the specific heat capacity of air at constant pressure, g is the gravitational acceleration, and z is the height above the surface. For turbulence in cloudy situations, it is necessary to consider the latent heat release in saturated parcels during adiabatic ascent and descent. Suitable conserved variables are liquid water potential temperature θ_l or liquid water static energy s_l and total water content q_t .

$$\theta_1 = \theta - \left(\frac{L_v \theta}{c_p T} \right) q_1, \quad [3]$$

$$s_1 = c_p T + gz - L_v q_1, \quad [4]$$

$$q_t = q + q_1, \quad [5]$$

where L_v is the latent heat of vaporization of water, and q_1 is the specific liquid water content. When clouds are present (i.e., $q_1 > 0$), q is equal to the saturation value q_{sat} at temperature T .

To quantify buoyancy and stability, a variable is needed that reflects the density of the fluid. For instance, static stability is determined by the density of a fluid parcel moved adiabatically to a reference height in comparison with the density of the surrounding fluid. The virtual potential temperature θ_v and the virtual dry static energy s_v are often used for this purpose:

$$\theta_v = \theta(1 + 0.61q - q_1), \quad [6]$$

$$s_v = c_p T(1 + 0.61q - q_1) + gz. \quad [7]$$

Surface Layer

The surface layer, also called the constant flux layer, is the lower part of the boundary layer where the fluxes are close to the surface values. The concept is an asymptotic one, with the constant flux layer assumption being valid only for heights that are small compared to the boundary layer height. In practice the criterion of a maximum of 10% deviation of the surface flux is often used. With a linear decrease of fluxes from the surface to the top of the boundary layer, it implies that 10% of the boundary layer depth can be considered to be the surface layer. So in a 1000-m deep daytime mixed layer, the surface layer has a depth of the order of 100 m, whereas in the stable nighttime boundary layer, which is only a few hundred meters deep, the surface layer can be as shallow as 10 m.

It is a common practice in turbulence models to use Monin–Obukhov (MO) similarity between the surface and the lowest model level. The theory of MO similarity is well established and the corresponding empirical functions have been the subject of extensive observational studies (Högström, 1988). Although MO similarity works well, in principle it is limited to stationary flow over homogeneous terrain. This is a serious limitation as flow in, e.g., NWP and climate models over real terrain, which is seldom homogeneous (Table 1).

The standard way of expressing (kinematic) surface fluxes of momentum $\overline{u'w'}_0$ and $\overline{v'w'}_0$, sensible heat $\overline{w'\theta'}_0$, and moisture $\overline{w'q'}_0$ into wind, temperature, and moisture differences over the surface layer is with the help of transfer coefficients (e.g., Brutsaert, 1982; Stull, 1988; Garratt, 1992):

$$\overline{u'w'}_0 = -C_m |\vec{U}_1| U_1, \quad [8]$$

$$\overline{v'w'}_0 = -C_m |\vec{U}_1| V_1, \quad [9]$$

$$\overline{w'\theta'}_0 = C_h |\vec{U}_1| (\theta_s - \theta_1), \quad [10]$$

$$\overline{w'q'}_0 = C_q |\vec{U}_1| (q_s - q_1), \quad [11]$$

where C_m is the transfer coefficient for momentum (drag coefficient), C_h is the transfer coefficient for heat, C_q is the transfer coefficient for moisture, $|\vec{U}_1|$ is the absolute horizontal wind speed at the lowest model level, θ_1 and q_1 are potential temperature and specific humidity at the lowest model level, and θ_s and q_s are potential temperature and specific humidity at the surface. (Over water θ_s and q_s are determined by the surface temperature and its saturation specific humidity (over the ocean humidity is only 98% of the saturation value due to salinity effects); over land, a surface scheme is needed to obtain θ_s and q_s .) In accordance with MO theory, the transfer coefficients can be written in terms of profile functions containing a logarithmic part, with roughness lengths as surface characteristics, and a stability function describing the effect of stability as a function of the Obukhov length:

$$C_m = \frac{k^2}{[\ln(z_1/z_{om}) - \Psi_m(z_1/L)]^2}, \quad [12]$$

$$C_h = \frac{k^2}{[\ln(z_1/z_{om}) - \Psi_m(z_1/L)][\ln(z_1/z_{oh}) - \Psi_h(z_1/L)]}, \quad [13]$$

$$C_q = \frac{k^2}{[\ln(z_1/z_{om}) - \Psi_m(z_1/L)][\ln(z_1/z_{oq}) - \Psi_h(z_1/L)]}, \quad [14]$$

where L is the Obukhov length ($= -u_*^3/(\overline{w'\theta'}_{vo} kg/\theta_v)$); k is the von Karman constant (0.4); $u_* = \{(\overline{u'w'}_0)^2 + (\overline{v'w'}_0)^2\}^{1/4}$ is the friction velocity; z_{om} , z_{oh} , and z_{oq} are the roughness lengths for momentum, heat, and moisture; z_1 is the height of the lowest model level (in many models between 10 and 30 m); and $\Psi_{m,h}$ are the stability functions for momentum and heat/moisture. Over land where z_1 is not necessarily large compared to z_{om} , a displacement height equal to z_{om} needs to be added to z_1 , but over the ocean this effect is negligible because $z_1 \gg z_{om}$. The transfer coefficients can also be written as

$$C_m = C_{mn} F_m(\text{Ri}_b, z_1/z_{om}, z_1/z_{oh}), \quad [15]$$

$$C_h = C_{hn} F_h(\text{Ri}_b, z_1/z_{om}, z_1/z_{oh}), \quad [16]$$

$$C_q = C_{qn} F_h(\text{Ri}_b, z_1/z_{om}, z_1/z_{oh}), \quad [17]$$

where the neutral transfer coefficients are defined by the logarithmic part of the profile functions

$$C_{mn} = \frac{k^2}{[\ln(z_1/z_{om})]^2}, \quad [18]$$

$$C_{hn} = \frac{k^2}{[\ln(z_1/z_{om})][\ln(z_1/z_{oh})]}, \quad [19]$$

$$C_{qn} = \frac{k^2}{[\ln(z_1/z_{om})][\ln(z_1/z_{oq})]}, \quad [20]$$

and F_m and F_h are the stability functions dependent on bulk Richardson number $\text{Ri}_b = (g/\theta_v) z_1 (\theta_{vs} - \theta_{v1}) / |\vec{U}_1|^2$, and the

ratios z_1/z_{om} and z_1/z_{oh} . It can easily be shown that Ri_b is related to z_1/L , so the functions F_m and F_h can be derived from the MO stability functions for which the main body of empirical information exists. In these expressions, the stability functions F_m and F_h also have a formal dependence on z_{oq} , which has been neglected here, because z_{oq} is often equal to z_{oh} and the stability dependence on moisture is weak.

An extension of the air-surface transfer framework has been to add a gustiness velocity in the definition of the absolute wind speed (Beljaars, 1995):

$$|\vec{U}_1| = (U_1^2 + V_1^2 + \beta w_*^2)^{1/2}, \quad w_* = \left(\overline{hw'\theta'}_{vo} g / \theta_v \right)^{1/3} \quad [21]$$

with h for boundary layer height, w_* is the free convection velocity scale, $\overline{hw'\theta'}_{vo}$ is the surface buoyancy flux, and β an empirical parameter. To include the effect of gustiness on the friction velocity, the friction velocity needs to be redefined as well

$$u_* = C_m^{1/2} (U_1^2 + V_1^2 + \beta w_*^2)^{1/2}. \quad [22]$$

Observational and model studies suggest β -values ranging from 0.8 to 1.25. The idea is that the horizontal wind (U_1, V_1) and the large-scale components of the horizontal wind fluctuations (scaling with w_*) control the air-surface coupling. Horizontal wind fluctuations do not obey MO similarity (they scale with h) and therefore this part of the air-surface transfer is an extension to MO theory. The gustiness effect is only important at low wind speeds since values of w_* vary typically between 0.5 and 1.5 $m\ s^{-1}$. However, it is necessary to include gustiness in the air-surface transfer to avoid the singularity at zero wind speed and to obtain a proper free convection limit.

The formalism described above leaves two aspects undefined namely; (1) the neutral transfer coefficients defined by roughness lengths, and (2) the stability functions. The stability functions have been subjects of a number of experimental programs and are reasonably well known for homogeneous terrain (Högström, 1988). Popular functions for unstable situations are

$$\Psi_m = 2 \ln \left\{ \frac{x+1}{2} \right\} + \ln \left\{ \frac{x^2+1}{2} \right\} - 2 \arctan(x) + \frac{\pi}{2}, \quad [23]$$

$$\Psi_h = 2 \ln \left\{ \frac{x^2+1}{2} \right\}, \quad \text{with } x = (1 - 16z/L)^{1/4}. \quad [24]$$

In the neutral limit with $|L| \rightarrow 0$, $\Psi_{m,h} \rightarrow 0$ (leaving just the logarithmic part of the transfer coefficients in eqns [12]–[14]) and $F_{m,h} \rightarrow 1$. For stable situations, the following functions are adequate for most applications (Beljaars and Holtslag, 1991)

$$-\Psi_m = a \frac{z}{L} + b \left\{ \frac{z}{L} - \frac{c}{d} \right\} \exp(-dz/L) + \frac{bc}{d}, \quad [25]$$

$$-\Psi_h = \left\{ 1 + \frac{2az}{3L} \right\}^{3/2} + b \left\{ \frac{z}{L} - \frac{c}{d} \right\} \exp(-dz/L) + \frac{bc}{d} - 1, \quad [26]$$

with $a = 1$, $b = 0.667$, $c = 5$, and $d = 0.35$. The evidence for having different Ψ_m and Ψ_h functions is very weak in the fully turbulent regime (i.e., $z/L < 1$), but necessary in very stable situations. With $\Psi_m = \Psi_h$, it can easily be shown that a critical Richardson number exists, beyond which no turbulence can exist. Practically, it is important that the conversion from Richardson number to z/L , which is necessary in large-scale models, does not become singular. The functions in eqns [25] and [26] guarantee such a regular behavior.

The last parameters that need specification in order to describe air-surface transfer are the roughness lengths for momentum, heat, and moisture. Roughness lengths are considered to be surface characteristics, but specifying them can be very difficult. The roughness lengths are as much part of the air-surface transfer problem as the transfer functions themselves.

For land, empirical tables are used that relate roughness lengths to vegetation cover and type (e.g., 0.03 m for smooth grass and 1–2 m for forest). However, heterogeneity in land cover has a big influence. Intermittent obstacles (e.g., lines of trees) can change a smooth surface into a surface that exerts a strong drag on the atmospheric flow. The standard way of handling surface heterogeneity in large-scale models is to define so-called effective roughness lengths. The effective roughness lengths are the ones that give the correct area-averaged flux in a large-scale model. The concept is justified by observations over heterogeneous terrain where far away from the surface a logarithmic profile is observed with a slope that corresponds to u_*/k , where the friction velocity is the square root of the *area-averaged* kinematic momentum flux at the surface (Mason, 1988). Far away means at such a distance from the surface that the internal boundary layers from the surface heterogeneities have blended. Another example of surface heterogeneity is subgrid orography, which exerts form drag on the flow. The effect of subgrid orography is often included in large-scale models through an enhanced roughness length. The orographic contribution to the ‘effective roughness length’ can be very large. In areas with orography, the roughness length for momentum can go up to a few hundred meters.

Much less is known about the roughness lengths for heat and moisture. For homogeneous low vegetation they tend to be an order of magnitude smaller than the roughness length for momentum, but the effect of terrain heterogeneity is less obvious. Indications are that the transfer coefficients for heat and moisture are not enhanced because the equivalent of pressure drag on obstacles (form drag) does not exist for heat and moisture, and therefore the roughness lengths for heat and moisture decrease when the roughness length for momentum has a heterogeneity or orographic enhancement. There are also indications that the roughness lengths for heat and moisture are not really surface properties but also depend on environmental parameters such as solar elevation, wind, and stability.

The notion that surface roughness lengths are an integral part of the air-surface transfer problem and the fact that roughness lengths over land can be rather uncertain have inspired other approaches. An example is the free convection transport theory for heat and moisture proposed by Stull (1994). It has transfer laws that do not depend on surface

characteristics, but the empirical coefficients are not the same for land and ocean.

Also, the use of an effective roughness for subgrid orography is rather unsatisfactory because the z_{om} values can become much larger than the height of the lowest model level. This makes the specification of roughness lengths for heat and moisture rather intractable. As an alternative for the effective roughness length concept, Beljaars et al. (2004) therefore proposed to implement turbulent orographic form drag as an additional tendency profile on model levels.

Roughness lengths over the ocean are much smaller than over land (between 10^{-5} and 10^{-3} m). Since ocean waves make the surface aerodynamically rough and since waves are wind driven, it is not surprising that the ocean roughness length for momentum scales predominantly with the friction velocity. A common expression is

$$z_{om} = C_{ch} u_*^2 / g + 0.11 \nu / u_*, \quad [27]$$

$$z_{oh} = 0.40 \nu / u_*, \quad [28]$$

$$z_{oq} = 0.62 \nu / u_*, \quad [29]$$

where the first term in eqn [27] represents the so-called Charnock relation for rough ocean waves with C_{ch} , the empirical Charnock parameter (common values range from 0.01 to 0.03). The second term with ν/u_* represents the scaling for molecular exchange, with ν for the kinematic viscosity of air ($1.5 \cdot 10^{-5} \text{ m}^2 \text{ s}^{-1}$). Neutral transfer coefficients in accordance with eqns [18], [20], [27], and [29] are given for the 10-m reference level in Figure 2 as a function of wind speed. There is a clear increase of C_{mn} with wind speed, whereas the transfer coefficient for moisture is fairly constant. Both transfer coefficients increase at low winds due to the ν/u_* scaling. The shown characteristics as a function of wind speed correspond very well with observations, although recent studies indicate that the transfer coefficients also depend on the state of the ocean waves often characterized by the wave age (Janssen, 2004).

Figure 2 Neutral transfer coefficients for momentum (dashed) and moisture (solid) as a function of wind speed for the 10-m reference level.

Bulk or Slab Model for the Dry Mixed Layer

Turbulent mixing is strong in the unstable boundary layer due to heating from the surface and therefore the outer part of the boundary layer (BL) (above the surface layer) tends to be well mixed in conserved variables (particularly θ but also U , V , and q). An obvious way of describing the well-mixed boundary layer is by describing the evolution of the BL by its depth, its mixed layer values U_m , V_m , θ_m , and q_m , and the jump in these conserved variables at the top of the BL (Driedonks, 1982, Figure 3 illustrates this bulk model). Simple rate equations can be derived for potential temperature with a mixed layer value θ_m and a depth h :

$$h \frac{d\theta_m}{dt} = \overline{w'\theta'}_0 - \overline{w'\theta'}_h, \quad [30]$$

$$\frac{dh}{dt} = w_e, \quad [31]$$

$$\frac{d\Delta\theta}{dt} = \gamma w_e - \frac{d\theta_m}{dt}, \quad [32]$$

$$\overline{w'\theta'}_h = -w_e \Delta\theta, \quad [33]$$

where $\overline{w'\theta'}_0$ is the kinematic surface heat flux, w_e the entrainment velocity, $\overline{w'\theta'}_h$ the flux at the top of the mixed layer, $\Delta\theta$ the temperature jump at the top of the mixed layer, and γ the lapse rate above the boundary layer. The total derivatives in eqns [30]–[33] include advection. This is not a closed set of equations; a closure equation is needed for entrainment flux $\overline{w'\theta'}_h$ or $\overline{w'\theta'}_{vh}$. This term has been studied extensively with tank experiments and in the atmosphere. Its magnitude is related to the amount of turbulent kinetic energy that is produced in the mixed layer and the fraction that is diffused

Figure 3 Schematic profile of potential temperature (θ) and kinematic heat flux profiles ($\overline{w'\theta'}$) in a simple slab model of the mixed-boundary layer.

into the inversion layer where it erodes the inversion. It is therefore plausible that this term scales with the total production of kinetic energy in the mixed layer. The following closure equation combines a number of production mechanisms in an empirical way

$$h(g/\theta_v)\overline{w'\theta'}_{vh} = B_1 u_*^3 + B_2 |\Delta \vec{U}|^2 w_e + B_3 w_*^3 + B_4 \sigma_w^3. \quad [34]$$

The empirical coefficients are by no means known accurately, but typical values are: $B_1 = 2.5$, $B_2 = 0.7$, $B_3 = 0.2$, and $B_4 = 1.5$. The first term represents the production of turbulence by shear in the mixed layer and scales with the surface friction velocity, the second one represents the production by shear in the inversion and scales with the velocity jump $\Delta \vec{U}$ over the inversion, the third term is often the dominant one as it represents the buoyancy production in the mixed layer, and the last term, scaling with the variance of the vertical velocity, represents the energy needed to spin up the calm air that is entrained into the mixed layer. Often in practical applications only the dominant third term is used, which corresponds to the well-known closure assumption $\overline{w'\theta'}_{vh} = 0.2\overline{w'\theta'}_{vo}$.

The advantage of bulk models is that they are simple and realistic (at least for well-mixed quantities), and do not rely on high vertical resolution. However, this type of model can be difficult to implement in a large-scale model as it involves a moving lower boundary (the top of the mixed layer). An alternative is to use the boundary layer height as a floating extra level to enhance the vertical resolution of a model at the inversion height where it is most needed. Furthermore, slab models have difficulties in handling less well-mixed boundary layers such as stable boundary layers, baroclinic boundary layers, and quantities that are not so well mixed such as wind and specific humidity.

Irrespective of whether mixed layer models are of practical importance, they are certainly of conceptual importance. The bulk model clearly illustrates the budget aspect of the well-mixed atmospheric boundary layer: the time evolution of the mixed-layer value is determined by the flux at the surface and the flux at the top. This is an aspect that should not be forgotten in more complex models: it is important to focus on the parametrization of the flux at the surface and on the flux in the inversion layer. The flux in between is automatically linear if sufficient mixing is present in the scheme.

K-Closure Based on Local Stability

A fairly simple closure for models that resolve the boundary layer explicitly is K -closure. This scheme (Louis, 1979) has become very popular in NWP and climate models. It follows MO similarity and in analogy with molecular diffusion, fluxes are assumed to be proportional to gradients

$$\overline{u'w'} = -K_m \frac{\partial U}{\partial z}, \quad \overline{v'w'} = -K_m \frac{\partial V}{\partial z}, \quad [35]$$

$$\overline{w'\theta'} = -K_h \frac{\partial \theta}{\partial z}, \quad \overline{w'q'} = -K_h \frac{\partial q}{\partial z}. \quad [36]$$

The exchange coefficients for momentum K_m and heat and moisture K_h are not a property of the fluid but depend on the

flow. Surface layer similarity provides expressions for K_m and K_h near the surface, which are

$$K_m = \frac{l^2}{\phi_m^2} \left| \frac{d\vec{U}}{dz} \right|, \quad K_h = \frac{l^2}{\phi_m \phi_h} \left| \frac{d\vec{U}}{dz} \right|. \quad [37]$$

The turbulence length scale $l = kz$ in the surface layer, with k for the von Kármán constant (0.4), and ϕ_m and ϕ_h are the MO stability functions for momentum and heat/moisture. This scheme is the differential form of what has been described above for the surface layer with $\phi_{m,h} = (1 - \eta \partial \Psi / \partial \eta)$, and $\eta = z/L$. Although these stability functions strictly apply only to the surface layer, they are also used above the surface layer, but the length scale has to be limited for large z , which is done by applying an asymptotic value λ in the following way (Blackadar, 1962)

$$\frac{1}{l} = \frac{1}{kz} + \frac{1}{\lambda}. \quad [38]$$

Typical values for λ are in the range of 30–300 m. This formulation works quite well for boundary layer turbulence but may be too active (dependent on the choice of stability functions) in the upper troposphere where clear-air turbulence can be significant. Therefore, some versions of the scheme gradually reduce the length scale in the upper troposphere by multiplying the length scale resulting from eqn [38] by, e.g., $\beta + (1 - \beta)/(1 + z/\lambda_a)$ with $\beta = 0.2$ and $\lambda_a = 4000$ m, which reduces the length scale to 20% of eqn [38] for heights well above 4000 m.

The expressions in eqn [37] contain the MO stability functions ϕ_m and ϕ_h , which are functions of l/kL (i.e., z/L in the surface layer), depend on fluxes. However, in a numerical model it is necessary to express the eddy diffusion coefficients in terms of model variables. The following relation between the gradient Richardson number and l/kL can be used

$$Ri = \frac{g}{\theta_v} \frac{d\theta_v/dz}{|d\vec{U}/dz|^2} = \frac{l}{kL} \frac{\phi_h}{\phi_m^2}. \quad [39]$$

The computational procedure is as follows: (1) compute the Ri number from the model variables, (2) solve eqn [39] for l/kL , and (3) substitute the result in eqn [37] to obtain the eddy diffusion coefficients. Depending on the precise form of the stability functions it may be necessary to solve eqn [39] iteratively or to store the relation between Ri and l/kL in a lookup table.

A numerically more efficient way of formulating this scheme is to put the empirical stability information in functions of the Richardson number (Louis, 1979). The eddy diffusion coefficients are expressed now in the following way

$$K_m = l^2 F_m \left| \frac{d\vec{U}}{dz} \right|, \quad K_h = l^2 F_h \left| \frac{d\vec{U}}{dz} \right|, \quad [40]$$

where F_m and F_h are empirical functions of the Richardson number and by definition $F_m = \phi_m^{-2}$ and $F_h = (\phi_m \phi_h)^{-1}$. Equation [40] is actually the closure equation that is used in many NWP and climate models. This formulation is known as the ‘Louis scheme.’ It is fully consistent with MO similarity in the surface layer and also with the concept of ‘local scaling’

for the stable boundary layer (Nieuwstadt, 1984). Typical stability functions are

$$\begin{aligned} \text{Ri} < 0 : F_m &= 1 - \frac{2b\text{Ri}}{1 + c_h(-\text{Ri})^{1/2}}, \\ F_h &= 1 - \frac{3b\text{Ri}}{1 + c_h(-\text{Ri})^{1/2}}, \end{aligned} \quad [41]$$

$$\begin{aligned} \text{Ri} > 0 : F_m &= \frac{1}{1 + 2b(1 + d\text{Ri})^{-1/2}}, \\ F_h &= \frac{1}{1 + 3b(1 + d\text{Ri})^{1/2}}, \end{aligned} \quad [42]$$

$$c_h = l^2/(3z^2), \quad b = 5, \quad c = 5, \quad d = 6. \quad [43]$$

An unsatisfactory aspect of the Louis scheme is that the stability functions $F_m = F_m(\text{Ri})$ and $F_h = F_h(\text{Ri})$ in NWP and climate models are inspired by large-scale model performance

rather than by observational studies. For the unstable boundary layer, the results are not very sensitive to the precise form of the stability functions, because the diffusion coefficients are large and the result will always be a well-mixed layer. However, in the stable boundary layer, results are very sensitive to the stability functions. Figure 4 shows two versions of functions that have been used in the European Centre for Medium-range Weather Forecasts (ECMWF) operational weather prediction model (Louis, Tiedtke, and Geleyn (LTG) after Louis et al., 1982; and a revised version of LTG) compared with functions that are observationally based for stable situations (Beljaars and Viterbo, 1998). The stability functions that are typically used in numerical models have much more mixing at high Richardson numbers than observed, but application of the observed MO functions leads to too stable near-surface layers as the result of a positive feedback with the land surface temperatures. The reason for the poor performance of observationally based functions in numerical models is a matter of speculation and subject of ongoing research. A number of reasons have been suggested (1) gravity waves at the top of the boundary layer

Figure 4 Stability functions for momentum and heat for the stable boundary layer as a function of the Richardson number. Three versions are shown: LTG and revised LTG (both of which have been used in the ECMWF model), and one that is derived from observationally based MO functions.

propagating into the stable boundary layer might break and cause extradiusion, (2) if the nighttime cooling is not distributed uniformly in the horizontal, mesoscale motion can maintain a higher level of mixing, and (3) effects of heterogeneity average nonlinearly and enhance the mixing. More research is obviously needed to clarify the missing physics and to find new formulations that are adequate for large-scale models. Currently, there are some interesting developments suggesting that nonlocal aspects play a role. The idea is that the stability above the stable boundary layers affects the mixing in the stable boundary layer by gravity wave interaction (Zilitinkevich, 2002).

Other unsatisfactory aspects of the Louis scheme are that for the mixed layer the fluxes can be upgradient (countergradient effects), and that entrainment at the top of the mixed layer is virtually zero with this formulation.

K-Profile Closure

An interesting closure which has been proposed by Troen and Mahrt (1986) for low-resolution models, as an alternative to the Louis scheme is the K-profile closure. In this scheme, the eddy diffusivity concept is used (eqns [35] and [36]), but the diffusion coefficients are specified as an integral profile for the entire boundary layer. The expressions for the stable boundary layer and for the unstable surface layer ($z/h < 0.1$) are

$$K_m = kw_s z \left(1 - \frac{z}{h}\right)^2, \quad [44]$$

$$K_h = kw_s z \left(1 - \frac{z}{h}\right)^2 Pr^{-1}, \quad [45]$$

$$w_s = u_* / \phi_h, \quad Pr = \phi_h / \phi_m \quad [46]$$

In the unstable outer layer, the same expressions are used except that w_s and Pr are evaluated at $z = 0.1h$ and that a countergradient term is introduced in the heat and moisture equations (the countergradient term is an extension of the eddy diffusivity concept and reflects the effect of large eddies in the convective boundary layer that cause transport irrespective of the local gradient):

$$\overline{w'\theta'} = -K_h \left(\frac{\partial \theta}{\partial z} - \gamma_\theta \right), \quad \overline{w'q'} = -K_h \left(\frac{\partial q}{\partial z} - \gamma_q \right), \quad [47]$$

$$\gamma_\theta = C \frac{(\overline{w'\theta'})_0}{w_s h}, \quad \gamma_q = C \frac{(w'q')_0}{w_s h}, \quad C = 8. \quad [48]$$

If the stability functions obey free convection scaling, this closure will automatically provide a velocity scale $w_s = (u_*^3 + C_1 w_*^3)^{1/3}$, with $C_1 = 0.6$ and $w_* = (h \overline{w'\theta'_{vo}} g / \theta_v)^{1/3}$. An essential part of this scheme is the diagnosis of the boundary layer top h , for which the following expression is used

$$h = \frac{Ri_c (U_h^2 + V_h^2)}{(g/\theta_v)(\theta_{vh} - \theta_{vs})} \quad [49]$$

Parameter Ri_c is a critical Richardson number with a numerical value of about 0.5, θ_{vs} is a virtual potential temperature somewhere in the surface layer (say 10 m above

the surface), and θ_{vh} is the virtual potential temperature at height h . For the convective boundary layer, the temperature θ_{vs} is augmented with the temperature excess that thermals have with respect to their surroundings:

$$\theta_{vs} = \theta_v + D(\overline{w'\theta'_v})_0 / w_s, \quad D = 6.5. \quad [50]$$

Different versions of this scheme are in use (Holtslag and Boville, 1993; Beljaars and Viterbo, 1998). The original scheme as described here leads to a too rapid boundary layer growth and therefore different modifications have been proposed. One of them is not to use the absolute wind speed at boundary layer height but to take the difference between the wind at level h and the wind at the 10-m level (Vogelezang and Holtslag, 1996).

The boundary layer top entrainment is not very well controlled in the original K-profile scheme and depends on the vertical distribution of levels. Therefore, it has been proposed not to use the K-profile in the inversion, but to parametrize the diffusion in the entrainment layer by imposing a virtual temperature flux of 20% of the surface value (as is done in bulk models).

The K-profile has a few major advantages. The first is its robustness from the numerical point of view. The reason is that no oscillations in K-profile can occur because it is specified (the Louis scheme has the well-known difficulty that it can easily lead to nonlinear instabilities for long time steps; see Kalnay and Kanamitsu, 1988; Beljaars, 1992). The second advantage is that the nonlocal aspects of the scheme allow for entrainment at the boundary layer top. In the original formulation, the entrainment is highly dependent on the vertical discretization, but imposing an entrainment flux cures the problem reasonably well. Finally, the scheme has a simple way of representing the countergradient effects, which are physically realistic although it is not entirely clear yet how important they are in real applications.

Figure 5 illustrates the effect of boundary layer top entrainment on the mixed layer moisture budget. Two versions of the ECMWF model are compared with observations in short range forecasts. The first version uses the Louis scheme (with LTG functions), but as discussed in the previous section, this scheme has no entrainment at all. The second scheme uses K-profile closure with an imposed entrainment rate of 20%. It is clear that the entrainment of dry air from above the boundary layer leads to a different moisture balance in the mixed layer and to a better correspondence with observations.

Higher Order Closure

The closure problem can be taken to another level by writing equations for the second moments. The resulting equations have triple correlations and pressure velocity correlations that are unknown and need closure assumptions. Many different formulations have been proposed; most of them are truncated versions of the full second-order equations. A good overview is given by Mellor and Yamada (1982) and a number of implementations in large-scale models exist. The simplest 'higher' order closure is the one in which the turbulence

Figure 5 Composite of nine diurnal cycles of First ISLSCP (International Satellite Land Surface Climatology Project) Field Experiment (FIFE) observations of specific humidity in August 1987 in comparison with 0–24 h forecasts from two versions of the ECMWF model (the LTG scheme and the K -profile scheme with a specified entrainment of 20% at the boundary layer top).

kinetic energy equation is used to estimate the velocity scale in the turbulent diffusion coefficients for momentum, heat, and moisture.

$$\frac{dE}{dt} = -\overline{u'w'} \frac{\partial U}{\partial z} - \overline{v'w'} \frac{\partial V}{\partial z} - \frac{g}{\theta_v} \overline{w'\theta'_v} - \frac{\partial}{\partial z} \left(\overline{E'w'} + \overline{p'w'}/\rho \right) - \varepsilon, \quad [51]$$

$$K_m = c_m l_m E^{1/2}, \quad K_h = c_h l_h E^{1/2}. \quad [52]$$

At the right-hand side of eqn [51], the first two terms represent the mechanical production of turbulence kinetic energy by shear, the third term is the buoyancy term which is a source term in unstable situations and a sink term in stably stratified flow, the fourth is the diffusion of turbulent energy by pressure fluctuations and by turbulence (it cancels out when vertically integrated), and the last term (ε) is the dissipation of turbulence kinetic energy by molecular friction (conversion into heat). Parameters c_m and c_h are empirical constants.

Before the energy equation can be used it needs closure equations for the diffusion term and for the dissipation term. Also the length scales need to be specified. The diffusion term can be closed by making the energy diffusion proportional to the gradient of the energy profile (K -diffusion) and by selecting a diffusion coefficient proportional to the ones for momentum or heat. The dissipation term is always parametrized in terms of the velocity and length scales of the energy containing eddies (i.e., $\sim E^{3/2}/l$) following the idea that the large eddies control the amount of energy that is transferred on the energy cascade toward the dissipating scales. The main advantage of the turbulent kinetic energy approach is that it has a natural way of generating boundary layer top entrainment. The energy produced by shear and buoyancy (mainly in the bulk of the boundary layer) is transported upward by the diffusion term into the inversion layer where it is absorbed by the negative buoyancy term (see Figure 6 for an illustration of the energy budget in the convective boundary layer).

Many different formulations exist for the length scale, varying from simple empirical functions of, e.g., height above the surface, stability, and boundary layer depth, to full prognostic equations. A popular alternative to the prognostic equation for the length scale is a rate equation for the dissipation rate with the length scale derived from $l \sim E^{3/2}/\varepsilon$. The advantage is that the length scale is a parameter that varies with environmental conditions (e.g., stability). However, parametrization of the unknown terms in the dissipation as

Figure 6 Illustration of the different terms in the kinetic energy budget in the unstable boundary layer. After Stull, R.B., 1988. *An Introduction to Boundary Layer Meteorology*. Kluwer, Dordrecht, Holland.

well as length scale equations is very difficult and data to support such parametrizations are virtually nonexistent.

Simplification of the full second-order equations to algebraic equations is an attractive alternative compared to the full equations. The eddy diffusivity terms and the countergradient terms come out rather naturally. Many flavors of such approximations exist and it is beyond the scope of this article to discuss them. A good overview of different levels of approximation is given in Mellor and Yamada (1982) and Holtslag and Duynkerke (1998).

The level of complexity that is needed depends very much on the application. Important aspects in NWP and climate models are entrainment, stable boundary layer diffusion, interactions with the cloud scheme, and perhaps countergradient effects. In a simulation of the internal boundary layer after a step change in surface roughness, simple models work well for the wind profiles, but energy and length scale (or ϵ) equations are needed to simulate the perturbed relations between fluxes and profiles. If one is interested in the evolution of the flow over a low hill, simple closure may do, but for the realistic simulation of the stress, it is necessary to use an advection equation for the stress (Beljaars et al., 1987).

Cloudy Boundary Layer

Boundary layer clouds have a strong impact on the boundary layer structure. The latent heat release due to condensation affects the buoyancy generation of turbulence, and the radiative effects of the clouds can change the energy budget of the boundary layer completely. Mixed layers that are driven by surface heating in the dry case can equally be maintained by radiative cooling at the cloud top as in a stratocumulus-topped boundary layer. Fog also becomes well mixed due to radiative cooling at the top as soon it is sufficiently thick. Shallow cumuli (e.g., in the trades) are very important for the drying of the boundary layer in the subtropics (boundary layer ventilation; Tiedtke, 1988) and therefore have a strong influence on the hydrological cycle. Finally, clouds are an important forecast

product in NWP and are an important modulator of the atmospheric radiative budget.

Standard turbulence schemes can be extended rather easily to situations with full cloud cover. An example is stratocumulus or fog. In this case, it is necessary to formulate the diffusion in terms of moist conserved variables (e.g., θ_1 and q_1) and to express the buoyancy in these variables. The latter is the main complication as due to the latent heat release in clouds and the water loading the formulation changes at the cloud base (see eqns [6] and [7] and Stull, 1988 for a discussion). A stratocumulus layer can be well mixed in the sense that the moist conserved variables are fairly uniform from the subcloud layer to the cloud top as the result of mixing through the entire boundary layer mainly driven by cloud top cooling. The key aspect in the modeling of a stratocumulus layer is the cloud top entrainment, which is not well understood. However, simple empirical relations exist (Lock, 1998). They couple the buoyancy flux in the inversion layer to the cloud top radiative cooling and the inversion strength (see Duynkerke, 1998; Lock, 1998) rather than to the surface buoyancy flux as in the dry mixed layer. That the boundary layer top entrainment is highly relevant in large-scale models is clear from the experience that models fill up large areas over the ocean with clouds when entrainment is not present or too small, and that stratocumulus disappears altogether when the top entrainment is too strong.

Shortwave radiation is another important factor in the evolution of a stratocumulus layer. In contrast to longwave radiation, which acts over a very shallow layer near the cloud top, solar radiation penetrates much deeper and therefore has the effect of enhancing buoyancy and decoupling the cloud layer from the subcloud layer. This can lead to breakup of the cloud due to two mechanisms. First, a stable layer near cloud base can be created which shuts off the moisture supply from the surface. Second, the enhancement of entrainment leads to additional drying and warming of the cloud layer. Proper modeling of the effects of solar radiation, the diurnal cycle, and decoupling is still very difficult.

Figure 7 illustrates the energy budget in a stratocumulus layer from a simulation with a turbulence energy equation

Figure 7 Profile of the different terms in the turbulence kinetic energy budget from a simulation of a stratocumulus layer by Duynkerke, P.G., Driedonks, A.G.M., 1987. A model for the turbulent structure of the stratocumulus-topped atmospheric boundary layer. *Journal of Atmospheric Sciences* 44, 43–64.

and a dissipation equation. The advantage is that no velocity and length scales need to be selected as they are both dynamically determined by the two equations. It is clear from the figure that the structure of the energy production is very complex with a sharp jump in the buoyancy term at cloud base. The diffusion term (labeled 'transport' in Figure 7) transports energy from the areas with production to stably stratified areas, e.g., the inversion. Dependent on the fluxes at the surface and at the top, the buoyancy minimum near cloud base can be negative, i.e., turbulence is damped here and so-called decoupling can occur. It is obvious that bulk mixed layer models, which can be used for a stratocumulus layer, break down when decoupling occurs.

Much more complex is the situation where partial cloudiness occurs as in fair weather cumulus or trade cumulus. Cumulus clouds are the result of condensation of the most powerful updrafts in the subcloud layer, and play an active role through the latent heat release in the cloud. There are two basic ways of handling the effects of shallow cumulus on the mixing: (1) to have a separate scheme to represent the mixing in the cloud layer in addition to a dry boundary layer scheme (e.g., Tiedtke, 1988), and (2) to have a moist turbulence model with a partial condensation scheme for the clouds (Cuijpers and Bechtold, 1995; Tompkins, 2002).

The idea of having a shallow convection scheme separate from turbulent diffusion is inspired by the observation that the processes are rather different. Although moist updrafts originate in the dry boundary layer, only some of the dry thermals make it into a cloud. Furthermore, analysis of turbulence generated by large eddy models suggests that transport in a shallow convection layer is most suitable for a mass flux scheme, whereas turbulent diffusion is more difficult to represent by mass flux transport only. The disadvantages of such a process splitting are that it creates difficulties in the transition from one process to the other at cloud base and that the transition to stratocumulus is not very well handled. In the latter case, a moist boundary layer scheme would be needed but such a scheme overlaps too much with a shallow convection mass flux scheme. Improving cloud and convection schemes and their coupling is an active area of research. Implementations have been made with intelligent switching between schemes (Brown et al., 2008) and by making shallow convection and boundary layer diffusion part of the same scheme through the so-called eddy-diffusion/mass flux approach (Siebesma et al., 2007; Köhler et al., 2011; Neggers et al., 2009).

The second way of handling clouds in the boundary layer is to use information on the fluctuations in T and q to decide about the cloud cover (as illustrated in Figure 8). The turbulent diffusion can be formulated in terms of moist variables and the partial cloudiness can be diagnosed making use of distribution functions for temperature and total water. Research has focused on the shape of the distribution functions and on how to couple them to turbulence schemes (Smith, 1990; Tompkins, 2002; Bechtold et al., 1995). Experience with large-scale models is that turbulence schemes tend to underestimate the variances (e.g., in T and q), which are needed to support a partial condensation scheme (see Smith, 1990). A possible explanation is that mesoscale variability has a nonnegligible effect on cloud fraction.

Figure 8 Illustration of how information on the variability of q and T can be used in a partial condensation scheme to estimate cloud fraction.

Introduction

With the advent of digital computers, weather forecasting was cast as a computational problem based on the fundamental prediction equations of fluids. Since analytic solutions are unavailable, approximations evolved to convert the differential equations to numerical equations suitable for computation on large computing machines. From this perspective, the concept of modeling was conceived. Thus weather forecasting – and more recently climate prediction – is approached by defining a numerical ‘model,’ and solutions to this model are sought. A variety of models have been developed over time to meet this goal, and the ‘spectral model’ is one of these.

The atmosphere is represented by variables describing molecular composites of its gases; the primary variables are velocity, temperature, density, water content in all phases, and aerosols. These variables are considered to be distributed continuously in three-dimensional space and to vary with time. The evolution of these variables in time may be determined at each point in space (the Eulerian method) or by following the particles through time (the Lagrangian method) and both methods are in use. The differential equations defining the future state of the variables are based on physical and dynamical principles, some well-known and others under study. These principles include the equations of motion (the Navier–Stokes equations), conservation of mass, an equation for change in entropy, equations for changes in water substance in its various phases, and chemical equations for changes of aerosols.

To define the notation of this article, these equations are presented below (*see Dynamical Meteorology: Primitive Equations*). Using the Eulerian reference, the time derivative is taken locally at each point in the fluid. The motion of the fluid is determined by an equation for the vector velocity $\mathbf{V}$ relative to the rotating Earth in all three space dimensions (eqn [1]).

$$\frac{\partial \mathbf{V}}{\partial t} = -(\mathbf{V} \cdot \nabla) \mathbf{V} - 2\Omega \times \mathbf{V} - \frac{1}{\rho} \nabla p - g\mathbf{k} + \mathbf{F} \quad [1]$$

Here, Ω is the angular velocity of the Earth; ρ and p are density and pressure, respectively, at each atmospheric point; g is the gravitational acceleration in the $\mathbf{k}$ (unit vertical vector) direction; and $\mathbf{F}$ comprises all frictional forces per unit mass. Conservation of mass is represented by the equation of continuity and the system thermodynamics are described by changes in entropy as in eqns [2]–[4].

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot \rho \mathbf{V} \quad [2]$$

$$\frac{\partial s}{\partial t} = -\mathbf{V} \cdot \nabla s + \frac{1}{T} q(q_v, q_i, q_l, a_j \dots); \quad 1 \leq j \leq J \quad [3]$$

$$\frac{\partial q_k}{\partial t} = Q_k \quad [4]$$

In eqn [3], s represents specific entropy, q is the rate of heating per unit mass, and T is the temperature. Additionally, q depends on the heating rates associated with water vapor (q_v), ice (q_i), liquid water (q_l), aerosols (a_j for $j = j_1$), and other factors such as radiation. Each of the variables q_j and a_j has its own prediction (eqn [4]), where the Q_k represent complex parametric formulae relating some or all of the dependent variables. This entire system of equations constitutes the basis for selecting the ‘model’ that is integrated in time to predict the future state of the fluid. Additional features needed to complete the model are boundary conditions, initial conditions, scale truncation, external forces, and computational resources.

The final step in constructing a model is to select a technique to convert the basic nonlinear differential equations that describe the forecast system (eqns [1]–[4]) into a numerical form suitable for computation and integration on a digital computer. Finite differencing in both the time and space dimensions was the first method attempted. Since the vertical and horizontal dimensions in the atmosphere have unique properties, they may be and often are considered separately. Given that at any given height in the atmosphere a closed spherical surface exists on which the dependent variables describing the fluid are prescribed and predicted, the spectral method, which assigns a set of known continuous orthogonal functions over the domain to represent these variables, may be applied. When all the variables are described in this way, the resulting equations are integrated over the global domain, leading to a set of ordinary nonlinear differential equations in time and on each vertical level. Concurrently, differentiation in the vertical space coordinate and time is normally, but not universally, transformed to finite differences. The spectral method is most appropriate for the larger space scales since the functions usually used are global. However, regional models can be cast in the spectral framework if the boundary conditions are suitable. Alternative methods that have been applied include finite elements and spherical geodesic grids.

In comparison with other modeling techniques, the spectral method has no pole problem; its resolution is essentially homogeneous and isotropic; it allows for a simple solution of the Helmholtz equation in various settings; and, with an appropriate choice of the transform grid, it produces nearly alias-free solutions. In addition to these advantages, it is also very computationally efficient. On the basis of these virtues, it has had a long run of success and has been the method of choice at many modeling centers.

Computational Methods

Models represented by finite differences are often denoted as grid point models and the grids for these models have been selected in a variety of ways. Despite their popularity, these models have many problems leading to significant computational errors, and the spectral method with its simple lateral boundary conditions over the globe is a natural alternative. Both methods are applied in the horizontal space domain, and are combined with an alternate discretization in both the vertical and time domains. The techniques were developed with the prediction equations represented in the Eulerian framework, that is, all calculations are made locally in the space domain, including time extrapolation of the dependent variables.

Although the structural characters of the two methods are substantially different, they can be cast in a similar representational form allowing for more systematic comparison. To elucidate this similarity, consider the dependent variables presented in the prediction equations (eqns [1]–[4]) represented by the vector $\mathbf{B} = \{B_b\} = (\mathbf{V}\rho s q_v q_1, q_i, a_j \dots)^T$, where T represents transpose. The dimensions of $\mathbf{B}$ are determined by the number of variables in the system; let that be N . As the equations stand, the left-hand side of the set is simply $\partial \mathbf{B} / \partial t$ and the right-hand side can be summarized by a vector $\mathbf{F}$ with the same dimension as $\mathbf{B}$ to yield the following system (eqn [5]).

$$\frac{\partial \mathbf{B}}{\partial t} = \mathbf{F}(\mathbf{B}, \mathbf{r}, t) \quad [5]$$

$\mathbf{F}$ depends both differentially and nonlinearly on $\mathbf{B}$, the space coordinates $\mathbf{r}$, and time. Altering these equations by a transformation with the linear matrix operator $\mathbf{L}$ leads to the more general form (eqn [6]) for the prediction system.

$$\mathbf{L} \frac{\partial \mathbf{B}}{\partial t} = \tilde{\mathbf{F}}(\mathbf{B}, \mathbf{r}, t) \quad [6]$$

Consider first the finite difference process applied to this system. Selecting a three-dimensional grid with M points to approximate the continuum in space with suitably prescribed boundary conditions, and a difference operator to describe derivatives, $\mathbf{B}$ is represented at each of the points and has dimensions $(N \times M)$; if the values of $\mathbf{B}$ are available at some initial time, a numerical integration can proceed. The matrix $\mathbf{L}$ becomes by virtue of the difference operator an $(N \times M) \times (N \times M)$ matrix, which can in principle be inverted, and $\mathbf{F}$ also becomes a numerical vector with $N \times M$ elements after utilization of the difference operator at each grid point. Using a circumflex to represent numerical vectors and matrices at grid points, the finite difference system is written as eqn [7].

$$\frac{\partial \hat{\mathbf{B}}}{\partial t} = \hat{\mathbf{L}}^{-1} \hat{\mathbf{F}}(\hat{\mathbf{B}}, \hat{\mathbf{r}}, t) \quad [7]$$

The solution is thus reduced to a matrix computation, provided a numerical scheme is introduced to step the variables forward in time, and the resulting computational errors and stability issues are dependent on the numerical and physical approximations made.

The spectral method uses a different approach. Given a continuous domain over which the model variables are to be evaluated, a set of linearly independent global functions that are continuous over the domain with at least continuous first and second derivatives are selected. The model variables B_b are

expanded in these functions with time-dependent coefficients. Thus, instead of a set of values for the B_b at each grid point $(i\Delta x_1, j\Delta x_2, k\Delta x_3)$ one has eqn [8], where Z_a are the global expansion functions (with their requisite properties).

$$B_b(\mathbf{r}, t) = \sum_{a=1}^{M_e} B_{b,a}(t) Z_a(\mathbf{r}) \quad [8]$$

The choice of these functions is arbitrary, but some guidelines may optimize their selection. It would be ideal to select functions that fit the observation points of the expanded variables exactly, but the distribution of observations is not sufficiently uniform to make this feasible. The expansion functions might be chosen to fit statistics of observations interpolated to a more uniform grid such that the least number of functions (N) was required to describe most of the variance of the variables at those points. Additionally, functions could be chosen that fit boundary conditions most efficiently and/or with convenient orthogonalization properties.

For application to the prediction system, eqn [8] is introduced into eqn [6]. To maintain the exact form of eqn [6], the series given by eqn [8] must be infinite. Using a truncated form creates the spectral model, and also generates errors analogous to those from reduction to a grid (eqn [7]). Selection of an optimum truncation is therefore a significant issue.

The operator L_b , often used with the spectral method, is a diagonal matrix with L_b elements because the system is always linearly decoupled. The scalar spectral representation of eqn [6] is thus eqn [9] and the variables remain nonlinearly coupled in the functions $\tilde{F}_b$.

$$L_b \frac{\partial \mathbf{B}_b}{\partial t} = \tilde{F}_b(\mathbf{B}, \mathbf{r}, t) \quad [9]$$

Substitution of eqn [8] into eqn [9] leads to the error eqn [10].

$$\sum_{a=1}^{M_e} \left(\frac{\partial B_{b,a}}{\partial t} L_b Z_a \right) - \tilde{F}_b = \varepsilon_b \quad [10]$$

To solve this system for the unknown expansion coefficients $B_{b,a}$, multiply eqn [10] by suitable test functions $\hat{Z}_k(\mathbf{r})$ and require the integral over the space domain to vanish, a least-squares error minimization procedure. The test functions must be continuous over the domain and can be arbitrary. In practice, they are frequently chosen to be the expansion functions, but this is not required. With this approximation, the prediction equations for the expansion coefficients become eqn [11], yielding $N \times M_e$ equations for the unknown quantities, $\partial B_{b,a} / \partial t$, which can be solved for $B_{b,a}$ at future times using a suitable time extrapolation procedure.

$$\sum_{a=1}^{M_e} \left(\frac{\partial B_{b,a}}{\partial t} \int L_b Z_a \hat{Z}_k dS \right) - \int \tilde{F}_b \hat{Z}_k dS = 0 \quad [11]$$

To cast eqn [11] in a form more comparable to the finite difference eqn [7], let $\mathbf{B}_b = (B_{b,a})$ and $\mathbf{Z} = (Z_a)$, both vectors with M_e elements. Additionally, assume that the test functions can be similarly represented, i.e., $\hat{\mathbf{Z}} = (\hat{Z}_k)$. Since the functions F_b are implicitly functions of $(\mathbf{r}, t)$ (see eqn [5]), their projection onto the expansion functions yields eqn [12].

$$F_b = \sum_a F_{b,a}(t) Z_a = \mathbf{Z}^T \mathbf{F}_b \quad [12]$$

Generating the coefficients $F_{b,a}$ is nontrivial, resulting from nonlinear combinations of the expansion coefficients $B_{b,a}$ and efficient procedures will be discussed subsequently. Using the defined vectors, eqn [11] becomes eqn [13], representing M_e equations for the expansion coefficients of each dependent variable.

$$\int \hat{\mathbf{Z}}_b \mathbf{Z}^T dS \cdot \frac{\partial \mathbf{B}_b}{\partial t} = \int \hat{\mathbf{Z}} \mathbf{Z}^T dS \cdot \mathbf{F}_b \quad [13]$$

To combine the N equations of eqn [13] into one expression, define the $M_e \times M_e$ matrices $A_b \equiv \int \hat{\mathbf{Z}}_b \mathbf{Z}^T dS$ and $A \equiv \int \hat{\mathbf{Z}} \mathbf{Z}^T dS$, and then create $(N \times M_e) \times (N \times M_e)$ matrices $A_L = \text{diag}(A_b)$ and $A_R = \text{diag}(A)$. Extended vectors for the expansion coefficients to include all the variables can be constructed such that $B_s = (B_b)$ and $F_s = (F_b)$, leading to an equation (eqn [14]) formally identical to the finite difference eqn [7].

$$\frac{\partial B_s}{\partial t} = A_L^{-1} A_R F_s \quad [14]$$

The corresponding grid point values from this spectral representation may be calculated at each point $(i\Delta x_1, j\Delta x_2, k\Delta x_3)$ for each dependent variable B_b by use of eqn [8].

Spectral Modeling

Since most significant prediction models represent their dependent variables on a grid of points in the vertical and use nonspectral methods on that grid, the subsequent discussion of the spectral method will focus on the horizontal domain of the model representation. This requires that the variables B_b be represented on K surfaces in the vertical, with the surfaces separated by the grid intervals, and the variables described in those surfaces by eqn [8].

When selecting appropriate spectral functions for the expansion eqn [8], in addition to fitting observations well, the functions should also be chosen with the properties of the system in mind. Several conditions have been accepted as suitable requirements. First, require the functions Z_a to satisfy the eigenvalue problem (eqn [15]).

$$L_b Z_a = -c_{b,a} Z_a \quad [15]$$

In practice, the selection of L_b almost always represents a conversion of wind components to vorticity and divergence, which is given by a linear differential operator. Application of this operator in eqn [15] leads to a variety of useful and simple functions. The second condition is to require the expansion functions to be orthogonal and normal over the domain in a Hermitian sense (eqn [16]).

$$\int Z_i Z_j^* dS = \delta_{i,j} \quad [16]$$

This condition is reasonably simple to satisfy, since most function sets can be orthogonalized. Finally, the test functions when selected as the expansion functions do not lead to a significant loss of generality, thus this condition is uniformly imposed as $\hat{\mathbf{Z}} = \mathbf{Z}$. Utilizing these three conditions greatly simplifies the calculations required to perform each prediction time step since both integrals in eqn [13] become diagonal matrices.

A variety of functions have been used for the expansion (eqn [8]), most satisfying the conditions just enumerated, with the selection depending on the degree of generality desired to approximate the general system (eqn [14]). When the atmosphere is represented on a channel with rigid boundaries at fixed northern and southern latitudes short of the poles, double Fourier series in latitude and longitude are found to be convenient expansion functions. They satisfy the boundary conditions easily and, because of the very simple addition rules for these functions, nonlinear products are rapidly calculated. For the full global domain approximated by spherical surfaces over the Earth, the obvious expansion functions that satisfy the boundary conditions are surface spherical harmonics (often denoted as solid harmonics), and they have become the functions of choice for spectral modeling. Surface spherical harmonics are constructed as the product of associated Legendre polynomials and complex exponential functions. Selecting coordinates in spherical surfaces such that $\mu = \sin \varphi$, where φ is the latitude, and λ is the longitude, normalized Legendre polynomials represent the latitudinal structures with the form of eqn [17].

$$P_n^m(\mu) \equiv \left[(2n+1) \frac{(n-m)!}{(n+m)!} \right]^{1/2} \frac{(1-\mu^2)^{m/2}}{2^n n!} \times \left(\frac{d}{d\mu} \right)^{n+m} (\mu^2 - 1)^n \quad [17]$$

These are polynomials of degree n with $n - m$ roots in the domain $-\pi/2 < \varphi < \pi/2$ and m roots at the poles. Together with Fourier series in longitude the solid harmonics are given by eqn [18].

$$Y_{n,m}(\lambda, \mu) = P_{n,m}(\mu) e^{im\lambda} \quad [18]$$

These are the complex expansion functions Z_a used in eqn [8] for the horizontal structures. All functions vanish at the poles except the zonal ones ($m = 0$), and these remain finite there. The indices (n, m) define the roots of the functions and thus may be considered scaling elements; that is, the larger the indices, the smaller the scales represented by the functions. An example is given in Figure 1, which shows the cellular structure of the function for fixed n and various values of m . The total number of cells over the domain remains the same because some of the roots appear at the poles, but the cell structures differ. It is convenient to represent the indices as a single complex index, say $\alpha = (n + im)$. The functions are orthogonal over their respective domains and normalized; this is expressed (in a Hermitian sense) as eqn [19] with integration taken over the surface of the unit sphere.

$$\frac{1}{4\pi} \int Y_\alpha Y_{\alpha'}^* dS = \delta_{\alpha,\alpha'} \quad [19]$$

The asterisk signifies complex conjugation, and δ is the Kronecker delta. If $L_b \equiv \nabla^2$ (the Laplacian operator), substitution of Y_α for Z_a in eqn [15] yields the eigenvalues (eqn [20]).

$$c_\alpha = n(n+1) \quad [20]$$

Thus, solid harmonics satisfy the conditions desired for suitable expansion functions.

Most atmospheric variables (B_b) are sufficiently smooth that, when expanded in these functions, the series converges

Figure 1 Cellular structure of solid harmonic functions for $n = 5$ and all allowed values of m . Reproduced from Baer, F., 2000. Numerical weather prediction. In: Zelkowitz, M.V. (Ed.), *Advances in Computers*, vol. 52. Academic Press, London, UK, pp. 91–157.

rapidly. That expansion takes the form eqn [21], where z_k is any selected vertical level and the series truncates at M_e .

$$B_b(\lambda, \mu, z_k, t) = \sum_{\alpha} B_{b,\alpha,k}(t) Y_{\alpha}(\lambda, \mu) \quad [21]$$

The range of (α) is $n \geq 0$ and, because of the complex nature of Fourier series, m takes both positive and negative values. When eqn [21] is introduced into eqn [14] and suitably integrated over the space domain, the resulting equations become a set of ordinary nonlinear differential equations in time for the expansion coefficients.

Spectral Vorticity Model

To better understand the details of this methodology, it is advantageous to simplify eqn [14] by approximations but still maintain a system that can describe the elements of the technique. The simplest appropriate system is represented by the barotropic vorticity equation (BVE). Consider a barotropic fluid, which exists if the thermodynamic variables are uniquely related to one another and are independent of position in the fluid. In this setting, fluid motions need consideration in only one horizontal surface and are independent of height. Assuming further that the fluid is incompressible, it is then also three dimensionally nondivergent. If no divergence is introduced at the upper and lower boundaries, no divergence exists in any horizontal surface. Finally, under the condition of hydrostatic equilibrium, the vertical component of velocity can be ignored. The horizontal velocity is then represented by two scalar variables, which themselves may be transformed to any other two scalar functions; because rotation plays such a major role in

atmospheric motions, vorticity and divergence are universally chosen. For the approximations stated, the divergence vanishes and hence the velocity is represented uniquely by the vorticity and the prediction equation for vorticity derived from eqn [1] is denoted the BVE.

Applying these approximations to eqn [1] and ignoring friction, the simplified equation of motion is eqn [22], where the subscript 2 denotes two dimensionality.

$$\frac{\partial \mathbf{V}_2}{\partial t} = -(\mathbf{V}_2 \cdot \nabla) \mathbf{V}_2 - 2\mathbf{\Omega} \times \mathbf{V}_2 - \frac{1}{\rho(p)} \nabla_2 p \quad [22]$$

The Earth's vorticity is expressed here as $2\mathbf{\Omega} = f\mathbf{k}$ with $f = 2\Omega \sin \phi$, the Coriolis parameter, and j is the latitude. Transform the velocity to rotation and divergence by the definitions (eqns [23a]–[23c]).

$$\mathbf{V}_2 = \mathbf{k} \times \nabla \psi + \nabla \chi \quad [23a]$$

$$\nabla \cdot \mathbf{V}_2 = \nabla^2 \chi \equiv \delta \equiv \text{divergence} \quad [23b]$$

$$\mathbf{k} \cdot \nabla \times \mathbf{V}_2 = \nabla^2 \psi \equiv \zeta \equiv \text{relative vorticity} \quad [23c]$$

The equation for predicting the vorticity (BVE) is established by applying the operator $\mathbf{k} \cdot \nabla \times$ to eqn [22] and substituting eqns [23a]–[23c], as in eqn [24].

$$\begin{aligned} \frac{\partial \zeta}{\partial t} &= -\mathbf{V}_2 \cdot \nabla \eta = -\mathbf{k} \times \nabla \psi \cdot \nabla \eta = -J(\psi, \eta) \\ \eta &\equiv \zeta + f \equiv \text{absolute vorticity} \end{aligned} \quad [24]$$

This equation represents a very simplified atmosphere but contains prominent features of the full atmospheric system and is a useful tool for evaluating prediction techniques.

Nondimensionalizing eqn [24] using the Earth's radius (a) for space and its rotation rate (Ω) for time, and noting that the Coriolis parameter becomes $f = 2\mu$, eqn [24] in terms of the stream function (ψ) is then eqn [25].

$$\frac{\partial \nabla^2 \psi}{\partial t} = -2 \frac{\partial \psi}{\partial \lambda} - F(\psi) \quad [25a]$$

$$F(\psi) \equiv \frac{\partial \psi}{\partial \lambda} \frac{\partial \nabla^2 \psi}{\partial \mu} - \frac{\partial \psi}{\partial \mu} \frac{\partial \nabla^2 \psi}{\partial \lambda} \quad [25b]$$

Indeed, $\psi = B$, the only variable remaining of the set B_n in eqn [21] and for only one k level. Equation eqn [25] contains a linear term and two quadratic nonlinear terms; these latter terms constitute F , the remains of F_b in [12]. A representation in terms of expansion coefficients $\psi_\alpha(t)$ is attained using eqn [15] for the Laplacian operator, eqn [21] for the expansion of ψ , and eqn [12] for expansion of F , yielding eqn [26].

$$\sum_{\alpha} c_{\alpha} Y_{\alpha}(\lambda, \mu) \frac{\partial \psi_{\alpha}(t)}{\partial t} = 2i \sum_{\alpha} m_{\alpha} \psi_{\alpha} Y_{\alpha}(\lambda, \mu) + \sum_{\alpha} F_{\alpha} Y_{\alpha}(\lambda, \mu) \quad [26]$$

As a final step, eqn [26] is multiplied by the test functions (in this case the conjugates of solid harmonics) and integrated over the unit sphere, noting orthogonality. This results in the prediction equation for each of the expansion coefficients (eqns [27a] and [27b]).

$$\frac{\partial \psi_{\alpha}(t)}{\partial t} = 2im_{\alpha} c_{\alpha}^{-1} \psi_{\alpha}(t) + F_{\alpha}(t) \quad [27a]$$

$$F_{\alpha}(t) = \int F(\psi) Y_{\alpha}^*(\lambda, \mu) dS \quad [27b]$$

It is evident how eqns [27a] and [27b] can be extended to involve more dependent variables and any number of levels in the vertical. However, if more variables exist in the system, these variables will be coupled nonlinearly through the coefficient F_{α} .

Suppose that the series for α is truncated at M_e as suggested. This implies that all values of ψ_{α} for $\alpha > M_e$ vanish. However, on calculating the nonlinear product $F(\psi)$, $\alpha \leq 2M_e$ coefficients F_{α} are generated; thus at each time step the number of nonvanishing coefficients could double. This complication is resolved in the spectral method by always ignoring all computations for $\alpha > M_e$.

The truncation of α at M_e is somewhat intricate since, from eqn [17], $n \geq 0$ and $n \geq |m|$, whereas $-m_{\max} \leq m \leq m_{\max}$. The set of all allowed indices is best described by the intersections of integers in a grid on an n, m plane as depicted in Figure 2. The allowed points fall on an infinite triangle bounded by the lines $n = \pm m$, but it is sufficient to present only the triangle for $m \geq 0$. All sequential values of n and m beginning at the origin are generally selected to satisfy convergence requirements for the dependent variables that they represent, but a relationship between maximum values must be chosen. Two options are preferred. The first, denoted as rhomboidal truncation, has a maximum value of $m_{\max} \equiv M$ (specified) and allows for all

Figure 2 The domain and allowable range of indices m and n for triangular and rhomboidal truncations. Reproduced from Baer, F., 2000. Numerical weather prediction. In: Zelkowitz, M.V. (Ed.), *Advances in Computers*, vol. 52. Academic Press, London, UK, pp. 91–157.

values of $n \leq |m| + M$ for each $|m| \leq M$. The corresponding figure (this configuration describes a parallelogram) is represented in Figure 2 and the notation is written as, for example, R30 if $M = 30$. The advantage of this truncation is that each planetary wave m is represented by the same number of expansion coefficients, thereby allowing equal resolution for all waves. However, since the energy of atmospheric flow decreases rapidly with increasing wave number (m), resolution of the shorter waves may be less important than for the longer waves. This observation leads to triangular truncation, in which $n \leq N$ for each $|m| \leq M$, with $N \geq M$, a predetermined integer. Usually N is selected equal to M and this option is described as a triangle in Figure 2 with the notation T30 if $N = 30$, for example. In terms of scaling, this truncation has some advantages. The ultimate choice for truncation is to optimize the resolution of the model in terms of the number of scales included and to minimize the computing requirements by selecting the fewest degrees of freedom compatible with resolution.

Interaction Coefficient Method

Since all prediction models are computationally intensive, the spectral method must compete in the efficient utilization of available computing resources. It is apparent from eqns [27a] and [27b] that most of the computing time required involves the calculation of the coefficients F_{α} and much effort has gone into optimizing this calculation. Early attempts followed the procedure of substituting the expansion series eqn [21] for ψ into eqns [25a] and [25b] to represent $F(\psi)$ and calculating F_{α} from eqns [27a] and [27b]. This results in eqns [28a] and [28b].

$$F_{\alpha}(t) = \frac{i}{2} \sum_{\beta} \sum_{\gamma} \psi_{\beta}(t) \psi_{\gamma}(t) I_{\alpha, \beta, \gamma} \quad [28a]$$

$$I_{\alpha, \beta, \gamma} \equiv (c_{\beta} - c_{\gamma}) \times \int \left(m_{\beta} Y_{\beta} \frac{\partial Y_{\gamma}}{\partial \mu} - m_{\gamma} Y_{\gamma} \frac{\partial Y_{\beta}}{\partial \mu} \right) Y_{\alpha}^* dS \quad [28b]$$

The indices β and γ go over the same range as α , which is determined by the selected truncation, and the integration is over the unit sphere. The integrals $I_{\alpha,\beta,\gamma}$ are denoted as interaction coefficients and have exact solutions. Applying eqns [28a] and [28b] in eqns [27a] and [27b] shows that the time change of any expansion coefficient of the set α depends on the coupling of all the coefficients allowed in the spectral domain (refer to Figure 2) and each couple is weighted by its own interaction coefficient. Since each index consists of two real numbers, the set of interaction coefficients can be as large as the largest allowed index to the sixth power. In actuality, because of the simple addition rules for trigonometric functions, the integration over longitude reduces this by one order. The vector of these coefficients can be stored and needs to be computed only once. However, the number of multiplications that must be performed at each time step is daunting as the truncation limit becomes large.

The more complex system (eqn [14]) can be represented identically to eqns [27a] and [27b] by simply increasing the number of expansion coefficients to include additional variables. But a shortcoming of using interaction coefficients concerns the convergence rate for the series of several dependent variables included in the general set (B_b) when expanded in global functions, in particular liquid water and precipitation. Significant truncation errors may ensue with time integration utilizing such functions.

Transform Method

A technique denoted as the transform method is an alternate procedure for calculating the coefficients F_α , yielding the same (or better) results than the interaction coefficient method. This technique involves the transformation of the integrand in eqn [27] onto a special numerical grid and solving the integral by quadrature. If the grid is selected appropriately, the integral is evaluated exactly and at a great reduction in computing cost. In the longitudinal direction, the quadrature is most conveniently done by a trapezoidal formula since it is known that eqn [29] holds.

$$\frac{1}{2\pi} \int_0^{2\pi} e^{im\lambda} d\lambda = \frac{1}{J} \sum_{j=1}^J e^{im\lambda_j} \quad [29]$$

The summation is taken over an equally spaced grid of points λ_j , and uses twice the number of points as the maximum wave number. Since the functions in latitude are Legendre polynomials, a Gaussian quadrature is preferred. In this case, the quadrature is such that eqn [30] holds and is exact if the polynomial H is of degree $2K - 1$ or less.

$$\int_{-1}^1 H(\mu) d\mu = \sum_{k=1}^K G_k(\mu, K) H(\mu_k) \quad [30]$$

The G_k are Gaussian weights and the grid points μ_k are the roots of the Legendre polynomial $P_K(\mu)$. The appropriate grid for this calculation contains all allowed values (λ_j, μ_k) as specified. The range of the grid points is determined by the functions of the integrand in eqns [27a] and [27b].

The derivatives in $F(\psi)$ (see eqn [25]) must be taken before evaluating the function on the grid. Based on eqns [18] and [17], the differentiation with λ is straightforward, but the

μ -derivative requires more information. The Legendre polynomials satisfy the differential eqn [31], where the coefficients b_α are constants, and this defines the latitudinal derivatives.

$$(1 - \mu^2)^{1/2} \frac{dP_\alpha}{d\mu} = b_\alpha P_{\alpha-1} - b_{\alpha+1} P_{\alpha+1} \quad [31]$$

Following this procedure, $F(\psi)$ is reduced to a quadratic series over the indices (β, γ) in terms of the complex exponential functions in longitude and the associated Legendre polynomials in latitude, both of which can be evaluated on the specified grid. The actual calculation proceeds as follows. First, the quadrature over longitude is taken (eqn [32]), where the sum goes over the value $J = 3M - 1$ if triangular truncation is chosen.

$$\begin{aligned} Fm_\alpha(\mu, t) &= \frac{1}{2\pi} \int F(\psi(\lambda, \mu, t)) e^{-im_\alpha \lambda} d\lambda \\ &= \frac{1}{J} \sum_{j=1}^J F(\psi(\lambda_j, \mu, t)) e^{-im_\alpha \lambda_j} \end{aligned} \quad [32]$$

The calculation is made over those latitudes μ specified from the quadrature (eqn [33]).

$$\begin{aligned} F_\alpha(t) &= \frac{1}{2} \int Fm_\alpha(\mu, t) P_\alpha(\mu) d\mu \\ &= \sum_{k=1}^K G_k(\mu_k, K) Fm_\alpha(\mu_k, t) P_\alpha(\mu_k) \end{aligned} \quad [33]$$

Since the polynomial under summation in eqn [33] is $H(\mu)$ and is the product of three Legendre polynomials less one order, and each has a maximum order of N , it can be shown that $K = (3N - 1)/2$.

Analysis of the computing requirements for eqns [32] and [33] indicates that the maximum number of calculations is proportional to N^3 , significantly less than the N^5 needed by the interaction coefficient method. When using the transform method with those variables that have unacceptable convergence properties yet contribute to eqn [7], their series representation is not essential. Their input is included directly into the quadrature formula by their distribution on the transform grid. Since all the forcing functions are summed over the grid before quadrature is completed, any singularities from individual terms are smoothed out and their effects are minimized.

History

Since the 1960s, spectral models have become by far the most popular representation for describing the global atmospheric prediction equations in computational form. They overcome many of the limitations inherent in finite difference models. Most international prediction centers have adopted this modeling procedure. Canada and Australia implemented the model in 1976, the National Meteorological Center of National Oceanic and Atmospheric Administration (NOAA) did so in 1980, the French in 1982 and the European Center for Medium-Range Weather Forecasts (ECMWF) in 1983. As an example of how the models have evolved, production spectral models at ECMWF have grown in resolution from T63 in 1983 to T213 in 1998 with experiments currently running at T319.

Mesoscale Atmospheric Modeling

RA Pielke, Sr., University of Colorado at Boulder, CO, USA

Synopsis

Mesoscale systems in the atmosphere are those in which the instantaneous pressure field can be determined accurately by the temperature field, but the winds, even in the absence of surface frictional effects, are out of balance with the horizontal pressure gradient force. The framework of mesoscale models is overviewed and shows that the models include a physics base core comprising the pressure gradient force, advection, and gravity, and all other physical processes that are parameterized using tuned modular representations of turbulence, longwave and shortwave radiation, cumulus, and stable cloud processes. Computational methods, lateral and initial boundary conditions, and model validation are some of the topics discussed.

Introduction

Atmospheric mesoscale systems are identified as those in which the instantaneous pressure field can be determined accurately by the temperature field, but the winds, even in the absence of surface frictional effects, are out of balance with the horizontal pressure gradient force. The pressure field, under this situation, is said to be 'hydrostatic.' Larger scale atmospheric features (which are called 'synoptic' weather features), in contrast, have a wind field that is close to a balance with the horizontal pressure gradient force. These large-scale winds are said to be near gradient wind balance. Atmospheric features that are smaller than the mesoscale have pressure fields in which wind acceleration is a significant component (which is referred to as the dynamic wind). The pressure gradient that causes this dynamic wind is called the nonhydrostatic pressure.

Atmospheric mesoscale models are based on a set of conservation equation for velocity, heat, density, water, and other trace atmospheric gases and aerosols. The equation of state used in these equations is the ideal gas law. The conservation of velocity equation is derived from Newton's second law of motion as applied to the rotating Earth. The conservation of heat equation is derived from the first law of thermodynamics. The remaining conservation equations are written as a change in an atmospheric variable (e.g., water) in a Lagrangian framework where sources and sinks are identified.

Each of these conservation equations can be written to represent the changes following a parcel of velocity, potential temperature (entropy), water in its three phases, other atmospheric gases and aerosols, and mass, including source-sink terms. Models, however, seldom express the conservation relations in a Lagrangian framework. The chain rule of calculus is used to convert to an Eulerian framework.

Several assumptions are typically made in the conservation equations. These include the neglect of small-scale fluctuation of density except when multiplied by gravity (this is called the Boussinesq approximation), the neglect of vertical acceleration relative to the differences between the vertical pressure gradient force and gravity (referred to as the hydrostatic assumption), and the neglect of all molecular transfers.

The first two assumptions have not been made in recent years in the models, however, since the numerical equations are actually easier to solve without these assumptions. Nonetheless, the spatial and temporal scales of mesoscale systems result

in the two assumptions being excellent approximations with respect to mesoscale-sized systems. The third assumption is justified since advection is much more significant at transfers of heat, momentum, water, and other chemical species, than molecular motion on the mesoscale.

These conservation relations that are written as a set of simultaneous, nonlinear differential equations, unfortunately, cannot be used without integrating them over defined volumes of the atmosphere. These volumes are referred to as the model 'grid volume'. The region of the atmosphere for which these grid volumes are defined is called the 'model domain.' The integration of the conservation relations produces 'grid volume averages,' with point-specific values of the variables called 'subgrid-scale values.' The 'resolution' of data is limited to two grid intervals in each spatial direction.

The result of the grid volume averaging produces equations for the local time derivative of the grid volume-resolved variable which includes 'subgrid-scale fluxes.' An assumption that is routinely made in all mesoscale models (usually without additional comment) is that the grid volume average of subgrid-scale fluctuations is zero. This assumption, often referred to as 'Reynold's averaging,' is actually only accurate when there is a clear spatial scale separation between subgrid scale- and grid volume-resolved quantities.

Mesoscale model equations have been solved in a Cartesian coordinate framework. Each coordinate in this system is perpendicular to the other two coordinates at every location. Most mesoscale models, however, transform to a generalized vertical coordinate. The most common coordinates involve some form of terrain-following transformation, where the bottom coordinate surface is terrain height or terrain surface pressure. The result of these transformations is that the new coordinate system is not orthogonal, in general. Unless this nonorthogonality is small, the correct treatment of non-hydrostatic pressure effects in mesoscale models requires the use of tensor transformation techniques, as opposed to the separate use of the chain rule on each component of velocity, separately. The use of generalized coordinate systems introduces additional sources for errors in the models, since the interpolation of variables to grid levels becomes more complicated.

The model variables also need to be defined on a specified grid mesh. When all dependent variables are defined at the same grid points, the grid is said to be 'nonstaggered.' When dependent variables are defined at different grid points, the grid

is called a 'staggered grid.' The grid meshes can also be defined with smaller grid increments in one region surrounded by coarser grid increments. Such a grid is referred to as a 'nested grid.' If the grid increments vary at all locations, with the finest grid in a specified volume, the grid is called a 'stretched grid.'

The subgrid-scale fluxes in mesoscale models are parameterized in terms of resolvable variables. Turbulence theory, as observed from atmospheric field campaigns over horizontally homogeneous landscapes, and for undisturbed atmospheric conditions, is the basis for all mesoscale model representations of the vertical subgrid-scale flux terms. The vertical fluxes are parameterized differently when the lowest 50 m or so of the atmosphere are unstably stratified and when it is stably stratified. The planetary boundary is typically represented by three layers: a thin layer of a few centimeters near the surface where laminar fluxes are important (called the 'laminar layer'), a layer above which extends upward tens of meters where wind direction with altitude is ignored (referred to as the 'surface layer'), and the remainder of the boundary layer where the winds approach the free atmospheric value (referred to as the 'transition layer'). Disturbed (unsteady) boundary layers are not parameterized accurately, however, by existing parameterizations. The effect of land surface heterogeneity has been included on the subgrid scale only as a weighting of the surface layer fluxes by the fractional coverage of each land surface type. This technique is called the 'mosaic' or 'tile' subgrid-scale surface flux parameterization.

In contrast to the vertical fluxes, horizontal subgrid-scale fluxes in mesoscale models have no physical basis. They are included only to horizontally smooth the model calculations.

The representation of the source-sink terms in the conservation equations can be separated into two basic types: those that are derived from basic concepts and those that are parameterized. The only basic source-sink terms in mesoscale models that are derived from fundamental physical concepts are the pressure gradient force, advection, and gravity. Neither of these two effects involves adjustable (i.e., tunable) coefficients, which is one method to separate fundamental terms in the conservation equation from a parameterization. The remainder of the source-sink terms needs to be parameterized. Almost all parameterizations currently used in these models are either box or vertical column representations.

The radiative flux terms are typically separated into shortwave and longwave fluxes. The shortwave fluxes, also called 'solar fluxes,' are separated into direct and diffuse irradiance. The direct irradiance is the nonscattered flux, whereas the diffuse irradiance is the scattered radiative flux from the Sun. The direct irradiance is sometimes further separated into visible and near-infrared components. In cloudy model atmospheres, parameterizations based on cloud liquid water content, or more crudely on arbitrary attenuation based on relative humidity in the model, are used. Typically, only diffuse irradiance is permitted for overcast model conditions. Some models weight the fluxes for partly cloudy skies, using weighted parameterizations for both clear and overcast sky conditions. Polluted atmospheres also require parameterization on their effect on solar irradiance, although only a few mesoscale models have explored this issue.

Longwave irradiance is from the Earth's surface and from within the atmosphere. Scattering of longwave radiative fluxes

is typically ignored, such that only upwelling and downwelling irradiances are parameterized. This type of parameterization is called a 'two-stream approximation.' The major absorbers and emitters represented in mesoscale model parameterizations are liquid and ice clouds, water vapor, and carbon dioxide. Clouds are usually parameterized as black bodies to longwave irradiance. The water vapor and carbon dioxide are represented by the path length through the atmosphere, and their concentrations along their path. As with solar radiative fluxes, mesoscale models seldom include parameterizations of longwave irradiance associated with pollution. This neglect is partially a result of the dependency of the absorption, transmissivity, and scattering of both solar and longwave irradiance on the specific chemical composition and size spectra of the pollution.

The phase changes of water and this effect on the conservation of heat source-sink term are separated into stable cloud, cumulus convective cloud, and precipitation parameterizations. Stratiform cloud parameterizations range in complexity from algorithms which instantaneously precipitate rain (or snow) when the model relative humidity exceeds a user-specified relative humidity (referred to as a 'dump bucket' scheme), to individual conservation equations for several categories of hydrometers (e.g., cloud water, rain water, ice crystals, snow, graupel, and hail). For the larger hydrometeors, a nonzero, finite terminal fall velocity is usually specified. More detailed microphysical representations, where cloud hydrometer spectra are classified into more size class intervals (called 'microphysical bin parameterizations') are also used.

The parameterization of cumulus cloud rainfall utilizes some form of one-dimensional cloud model. These are called 'cumulus cloud parameterization schemes.' Their complexity ranges from instantaneous readjustments of the temperature and moisture profile to the moist adiabatic lapse rates when the relative humidity exceeds saturation, to representations of a set of one-dimensional cumulus clouds with a spectra of radii. These parameterizations typically focus on deep cumulus clouds, which produce the majority of rainfall and diabatic heating associated with the phase changes of water. Cumulus cloud parameterizations remain one of the major uncertainties in mesoscale models, since they usually have a number of tunable coefficients, which are used to obtain the best agreement with observations. Also, since mesoscale model resolution is close to the scale of thunderstorms, care must be taken so that the cumulus parameterization and the resolved moist thermodynamics in the model do not 'double count' this component of the source-sink terms.

The grid volume-averaged conservation equations are nonlinear and, therefore, must be solved using numerical approximation schemes. The solution techniques include finite difference, finite element, interpolation (also called semi-Lagrangian), and spectral methods. Both temporal-spatial terms and the source-sink terms must be represented by these approximation schemes. An important aspect of mesoscale models is that only advection and the pressure gradient force involve horizontal gradients explicitly. All other model terms, including each of the source-sink terms, are one-dimensional column models or point values.

Finite difference schemes involve some form of truncated Taylor series expansion. The finite element technique uses

a local basis function to minimize the numerical error, whereas the spectral method utilizes global basis functions. A spectral method has the advantage that differential relations are converted to algebraic expressions. The semi-Lagrangian scheme is based on fitting interpolation equations to data at a specific time and advecting the data with model winds.

Mesoscale models have predominately utilized the finite difference and (for advection) the semi-Lagrangian approaches. A few groups have applied the finite element method, but its additional computational cost has limited its use. The spectral method, which is most valuable for models without lateral boundaries, has not generally been used since mesoscale models have lateral boundaries.

The use of numerical approximations introduces errors. Linear stability analyses show that it is impossible to create a numerical solution scheme which accurately represents both amplitude change over time and speed of motion (advection and gravity wave propagation) for features that are shorter than about four grid increments in each spatial direction. In addition, products of the variables (which are a nonlinear terms) produce transfers of spatial scales to larger and smaller scales. The inability of the numerical model to sample the smallest scales (less than two grid intervals) results in the information (e.g., winds and temperature) erroneously appearing at a larger spatial scale. This error is called 'aliasing' and unless corrected can result in an incorrect accumulation of atmospheric structure at the wrong spatial scale. For these reasons, the term 'model resolution' should be reserved for features that are at least four grid intervals in each direction.

To integrate the models forward in time, the variables must be initialized. These values are called 'initial conditions.' Observed data, or a combination of observed data and previous model calculations, are typically used to initialize the mesoscale models. The insertion of data during a model calculation is called 'four-dimensional data assimilation (4DDA).' Lateral, top, and bottom boundary conditions are also needed for the duration of the model calculations. Lateral boundary conditions in mesoscale models can be idealized for theoretical studies (e.g., cyclic boundary conditions), or derived from large-scale observations, such as the NCEP Reanalysis or from larger scale model simulations (which is referred to as dynamic downscaling). Mesoscale models are often strongly influenced by the lateral boundary conditions, such that their accurate representation is a necessary condition for an accurate mesoscale simulation.

The top boundary conditions are similar to the lateral boundary condition and must be accurately represented. Most mesoscale models extend into the stratosphere, in order to minimize the effect of the model top on the mesoscale simulation. Damping zones at the model top (referred to as an 'absorbing layer') are usually inserted so that upward propagating model simulated gravity waves do not erroneously reflect from the artificial model top.

The surface boundary is the only surface of a mesoscale model which is physically based. This surface is typically separated into ocean (and fresh water lakes) and land surfaces. Ocean and lake surfaces can be represented simply as prescribed sea surface temperatures or using mesoscale atmospheric models coupled to mesoscale ocean, lake, and/or sea ice models. Over land, the ground is separated into bare soil and vegetated land. Soil-vegetation-atmosphere transfer

schemes (SVATS) have been introduced to represent the fluxes of velocity, heat, moisture, and other trace gases between the atmospheres and the surface. Most SVATS include the effect on water flux of transpiration. Recently, vegetation dynamical processes, such as plant growth have been included in longer term (months to seasons) mesoscale model calculations.

Model performance is assessed in several ways. The comparison of observations with model results using statistical skill tests is a major assessment tool. A complication of these evaluations is that observations have a different sampling volume (e.g., a point) than the model grid volume. Comparisons of simplified (usually linearized) version of numerical models with analytic theory have been completed to test the accuracy of linear components of the model. Several models can be intercompared to assess what features they have in common, and which they do not. The mass and energy budgets of the mesoscale models, if they are each calculated in two separate manners, provide an opportunity to check the internal consistency of the model. Peer-reviewed scientific publications and the availability for scrutiny of the model source code provide two additional valuable procedures to assess the value of the mesoscale model and the degree to which the programmed model logic agrees with the mathematical formulations presented in the literature. Proposals have been made to standardize the model computer codes, in order to assist in their more general use.

Mesoscale models have been applied to two basic types of mesoscale systems: those found primarily by initial and lateral boundary conditions (referred to as synoptically forced mesoscale systems) and those forced by surface boundary conditions (referred to as surface-forced mesoscale systems). Of the latter type, there are mesoscale systems that are caused when terrain is an obstacle to the flow (referred to as 'terrain-forced' or orographic mesoscale systems) and those generated by horizontal gradients in sensible heating of the surface (called 'thermally forced' mesoscale systems).

With the improvement in computational power, global models will soon approach mesoscale spatial and temporal resolution (which requires horizontal grid increments of ~ 1 km). This high resolution will eliminate lateral boundary conditions as a component in the accurate simulation of mesoscale atmospheric features models.

Synopsis

Aerosols and their effects on clouds and precipitation are one of the key components of the climate system and the hydrological cycle. Cloud-system resolving models (CRMs) with explicit microphysics can allow interactive processes between aerosols, cloud and precipitation for convective precipitation systems, hurricanes and other severe weather systems. CRMs can be used to improve our understanding of: (1) the impact of cloud condensation nuclei (CCN) and Ice nuclei (IN) on cloud and precipitation microphysics and (2) the associated important cloud dynamic processes. High-resolution observations from remote sensing would be a necessary part of the CRM validation through state-of-the-art multi-instrument satellite simulators.

Convective Precipitation Systems and Aerosols

Convective precipitation systems (CPSs) contribute to a major fraction of global rainfall distributions and latent heat release in the atmosphere, and their associated stratiform and anvil cover play one of the foremost roles in the Earth's radiation budget. Deep convection transports aerosols, mass, and momentum from planetary boundary layer (PBL) to middle- and upper-troposphere, and play important roles in atmospheric chemistry processes. CPSs could also produce strong wind gusts, downburst, hailstones, heavy rainfall, and lightning that are all harmful consequences on daily human life. Thus, understanding of the formation of the CPS characteristics is imperative for weather prediction and climate projection for our society.

Primal fuels (energy) of CPSs are surface turbulent heat fluxes and large-scale circulation (i.e., instability in atmosphere). Depending on the heat source and surrounding environmental conditions, surface air mass, hereafter denoted as *parcel*, can be lifted up to tropopause (~16 km above ground level) with the bubbly turbulent forms, and eventually shows the characteristic of anvil shape in the maturity stage (see more details in Houze, 1993). During the convection process, a parcel experiences complex cloud microphysics processes interacting with atmospheric aerosols.

When a parcel ascends from near surface, saturation is attained to form cloud droplets upon cloud condensation nuclei (CCN), which are derived from various water-soluble atmospheric aerosols:

$$N_{CCN} = \int_{D_{CRIT}}^{\infty} n(D) dD \quad [1]$$

where D is aerosol diameter; $n(D)$ is aerosol number concentrations; D_{CRIT} is a critical diameter for a given supersaturation rate, solute mass and types, and temperature based on the Köhler equation (which describes the equilibrium saturation ratio over the solute drop surface as a function of the drop radius). In general, a large number of water-soluble aerosol particles tend to increase the CCN number and, thus, cloud droplets. The large number of small cloud droplets competes for available moisture for condensation growth: thereby, cloud

droplets stay in relatively small size, which inhibits collision and coalescence processes to generate submillimeter-sized drizzle drops. Consequently, the large number concentrations of cloud droplets can inhibit warm-rain initiation.

If the parcel is lifted further, these small cloud droplets could be cooled to less than 0 °C without immediate freezing. In this temperature zone, aerosol particles start acting as ice nuclei (IN). The surface of supercooled cloud droplets start contacting with freezing aerosol particles through diffusiophoresis, thermophoresis, and Brownian motion or drop evaporation, and then cloud droplets are catalyzed to form embryo of ice crystals (i.e., contact/evaporation nucleation). Ice crystals can also be formed through immersing freezing aerosol particles with supercooled cloud droplets (i.e., immersion nucleation). Besides these nucleation pathways, ice crystals can also be formed directly upon nonsoluble aerosols by deposition (i.e., primal nucleation) or freezing right after condensation (i.e., condensation nucleation). Without interacting with nonsoluble aerosols, pure cloud droplets must be cooled down to at least -38 °C to form ice crystals (i.e., homogeneous nucleation). These various ice nucleation processes release latent heat by fusion and deposition that may further assist lifting the parcel.

Ice crystals keep growing by deposition of water vapor and/or aggregation processes with other ice crystals. In the convective core, the supercooled cloud droplets collide and freeze upon snowflakes surface (i.e., riming process) to form higher-density snowflakes. Once riming dominates, these particles are denoted as graupel or hail, which induce intensive cold-phase rainfall (see more details in microphysics from Pruppacher and Klett, 1997). While much more effort is required to understand the source of the IN precursor, DeMott et al. (2010) collected various field measurements, and found that measured IN concentrations, N_{IN} , can be well predicted from the concentrations of large-sized aerosol number concentrations ($N_{aero0.5}$) through the following equation (DeMott et al., 2010).

$$N_{IN} = a T^b N_{aero0.5}^{(cT+d)} \quad [2]$$

where

$$N_{aero0.5} = \int_{0.5\mu m}^{\infty} n(D) dD$$

D is the diameter of aerosols; $n(D)$ is aerosols number concentrations for a given diameters; T is air temperature; a , b , c , and d are fitted coefficients. Equation [2] is based on the summary of *in situ* measurements implying that the large concentrations of large-size aerosols in colder air temperature tend to increase the production of ice crystals and release more latent heat in the middle- to upper-troposphere.

Increased ice particles aloft could enhance the amount of ice transported to upper-troposphere. At this level, strong environmental wind together with convection-induced wind can horizontally spread out cloud particles to form the prominent anvil shape. Thus, enhanced ice production due to high aerosol concentrations could enhance the high cloud coverage, which tends to block incoming shortwave radiation from the Sun and trap outgoing long-wave radiation from the Earth's surface.

Overall, high concentrations of aerosols serving as CCN or IN could (1) delay onset of warm-rain process, (2) increase amount of supercooled water and riming process, (3) enhance ice concentrations and aloft, and (4) therefore, invigorate the cold-rain process. However, with enough energy and updraft speed, liquid cloud droplets could be lifted to the mixed-phase zone with little chance of warm-rain process regardless of variability of aerosol loading. More importantly, the presence of vertical wind shear organizes deep moist convection into the long-lasting larger forms, so-called mesoscale convective systems (MCSs). MCSs propagate for a given background wind and internal gravity wave, and a combination of updraft and downdraft could enhance ice production significantly (see more details in Houze, 1993). In this system, mesoscale cloud dynamics could dominate microphysics processes, secondary convections, and subsequent rainfall amount. Since aforementioned hypothesis of aerosol-CPS interaction would strongly depend on a case-by-case basis, first of all, it would require validating the observations extensively in time and space.

Satellite-Based View of Microphysics in CPSs

The aerosol-CPS interactions can be viewed from the satellite remote sensing on a global scale. Satellite-retrieved aerosols and

reanalysis-derived thermodynamic fields are averaged over the June–July–August period in 2006. Figure 1(a) depicts undiluted plume height (UPH) estimated from atmospheric reanalysis (MERRA: Modern Era Retrospective-Analysis for Research and Applications). Deeper moist convection more likely occurs over a higher-UPH area, such as Pacific Warm Pool, whereas it is inhibited over a lower-UPH area, such as a subtropical continental area in the southern hemisphere. Figure 1(b) depicts distribution of aerosol optical thickness (AOT) retrieved from Multiangle Imaging Spectro Radiometer (MISR) on the Terra satellite. In general, higher AOTs can be linked to larger concentrations of aerosols and CCN/IN concentrations.

In the corresponding period, precipitation radar (PR) 14 GHz echo from the Tropical Rainfall Measuring Mission (TRMM) satellite have been sampled on every 1×1 -gridded box over the same domain, and estimated maximum echo-top height (H_{ET}) during the 3-month period (Figure 1(c)). Elevated PR echo represents deeper convection due to raining of particles (snow and graupel) aloft into middle- to upper-troposphere, since the TRMM PR sensor is sensitive to rain-drops or relatively large ice particles. In a similar sampling manner, TRMM Microwave Imager (TMI) polarization-corrected brightness temperature at 85 GHz ($PCTb_{85}$) has been sampled. Figure 1(d) shows the depression in brightness temperature ($dPCTb_{85} = PCTb_{85,max} - PCTb_{85,min}$). With the presence of high-density solid precipitating drops (graupel or hail), microwave emission at 85 GHz from the Earth's surface can be scattered back to the surface; thus, larger $dPCTb_{85}$ generally represents the presence of a large amount of rimed ice particles (see more details in Matsui et al., 2009). In short, the higher PR H_{ET} and the larger $dPCTb_{85}$ represent the CPSs associated with the enhanced cold-rain process, which appear to be distributed in the high UPH regions. However, the very large PR H_{ET} (>15 km) and $dPCTb_{85}$ (>80 K) are mainly distributed over the continent with high aerosol loading estimated from MISR, including in middle to West Africa, northwest India, and the central to western portion of the United States.

From the brief satellite-based view, Figure 1(a)–1(d) supports the hypothesis of aerosol-CPSs interaction that

Figure 1 (a) MERRA-estimated undiluted plume height (UPH, defined as the maximum height that a near-surface parcel can be lifted by buoyant force without entraining surrounding air), (b) MISR-derived AOT, (c) TRMM PR-derived maximum H_{ET} , representing storm height, and (d) TMI-derived polarization-corrected brightness temperature depression at 85 GHz ($dPCTb_{85}$), most likely represents column amount of rimed particles.

higher aerosol concentrations tend to invigorate the cold-phase rainfall process in deep moist convection. However, a problem of observational analysis is the interpretation of statistical correlation and time evolution (life cycle) of CPSs. Satellite-based examination relies on a statistical summary of instantaneous observations; technically, it does not follow the life cycle of CPSs. Indeed, statistical analysis cannot conclude cause-and-effect relationship between aerosols and CPSs. Therefore, together with observational support, cloud-scale resolving atmospheric models (horizontal grid spacing of 0.25–3.0 km) with full microphysical interactions are also required to investigate details in the time evolution of and interactions between cloud–precipitation microphysics, meso-scale dynamics, and aerosols.

Cloud-System Resolving Modeling and Microphysics

Cloud-System Resolving Model

One of the most promising methods to test the representation of the detailed aerosol–cloud interaction process is to use explicit microphysics in cloud-system resolving models (CRMs) (see a recent review by Tao and Moncrieff, 2009). There are several major advantages in using CRMs to study the interactive processes between cloud, precipitation, and aerosol. For example, (1) unlike convective parameterization in climate models or general circulation models, CRMs employ a high-resolution, nonhydrostatic dynamic core to simulate the life cycle of CPSs; (2) the use of a fully explicit microphysics

scheme (liquid and ice) and a fine horizontal resolution can provide realistic evolution of cloud structures, optical properties, and latent heat release, which are crucial for determining the atmospheric energy budgets. One major limitation of CRMs is its inability to represent interactions between cloud/cloud system-scale dynamics and synoptic dynamics due to relative limited domains coverage.

Microphysics

Two-moment bulk and spectral-bin microphysics schemes are generally required to study the impact of the CCN, giant CCN (GCCN), and IN on cloud and precipitation formations. Typically, two-moment bulk microphysics schemes predict both mass and number concentrations of each hydrometeor with more than 25 microphysical transfers occurring among water vapor, liquid, and ice particles. These processes include growth of ice crystals by vapor deposition and riming, the aggregation of ice crystals, the formation of graupel and hail, the growth of graupel and hail by the collection of supercooled raindrops, the shedding of water drops from hail, the rapid growth of ice crystals in the presence of supercooled water, and the melting and sublimation of all forms of ice (Figure 2). With increasing computer power, explicit bin microphysical schemes have been developed for CRMs to study cloud–precipitation–aerosol interaction. One of the major differences between the two-moment bulk and spectral-bin microphysics schemes concerns the representation of the cloud particles size (Figure 3). Unlike assumed shape (such as

Figure 2 Schematics of the bulk microphysical processes in the typical two water and three-class ice scheme. Boxes represent the bulk classes of water and aerosol particles, and the arrows represent conversion pathways with plus and minus signs indicating direction of the named conversion process. In addition to prediction the mass of cloud water species (cloud drops, rain, cloud ice, snow, and graupel), the number of concentration of cloud water species is also predicted. gamma distributions) of particle size distributions (PSDs) in two-moment bulk microphysics, each type is described by a discretized size distribution containing as much as 30 or more size sectors (bins) (Figure 3). The formulation of the explicit microphysical processes is based on solving equations of mass advection by condensation growth and stochastic collision kinetics for the size distribution functions of water droplets (cloud droplets and raindrops together as one category). Ice particles are much more complicated due to their different shapes, so they are often classified into various growth habits such as columnar, platelike, dendrites, snowflakes, graupel, and frozen drops. Spectral-bin microphysics has also been used to improve the performance of bulk microphysics.

Results

CRMs have been used to examine the role of aerosols on CPSs. These modeling studies had many differences in terms of model grid configuration (two- or three-dimensional), domain sizes, grid spacings (150–3000 m), microphysics (i.e., two-moment bulk, spectral-bin), turbulence (simple or high order), radiation (with or without radiation effect), lateral boundary conditions (i.e., closed, radiative open, or cyclic), types of CPSs (isolated convection, tropical, or midlatitude squall lines), and model integration time (e.g., 2.5–48 h). Among the cloud-resolving modeling studies, the most striking difference is that cumulative precipitation can either increase or decrease in response to higher concentrations of CCN.

CCN Effect on Cloud Droplets Spectra

It is commonly believed that clouds in a clean environment (low CCN concentrations) produce fewer cloud droplets with

larger sizes due to greater condensational and collectional growth, leading to a broader size spectrum in comparison to a polluted environment (high CCN concentrations). Figure 4 shows the CRM with spectral-bin microphysics simulated PSDs of cloud droplets under low and high CCN concentrations for an oceanic and a continental convective case. Smaller cloud droplets with narrow PSDs were well predicted under a polluted environment (2520 of N_{CCN}), while larger cloud droplets with wider PSDs were predicted under a clean environment (600 of N_{CCN}). These basic features are well predicted by CRM simulations with either two-moment or spectral-bin microphysics in good agreement with the hypothesis and observations (Pruppacher and Klett, 1997), indicating that the cloud microphysics depends strongly on cloud–aerosol interactions. The broader or narrower PSDs could have an impact on the drizzle processes; i.e., the smaller cloud droplets would reduce the chance to form raindrops from cloud drop coalescence. Figure 4 also shows that cloud droplets with the diameter greater than 40 μm are not present in a polluted environment.

Impact of CCN on Precipitation

CRMs have been used to quantify the aerosol impact on rainfall associated with deep CPSs under different environments as well as different types of convective systems. Warm-phase rain suppression in the high CCN concentration (i.e., polluted environment) is evident in almost all case studies but only within the first hour during CRM integrations (Figure 5). In clean environments, warm-rain processes are initiated earlier than polluted environments, and rain reaches the ground early in all the clean-environment cases. This result clearly suggests that the microphysical processes dominate the initial stage of cloud evolution and rainfall. This is because that compared to the case in polluted conditions,

Figure 4 CRM-simulated cloud drop size distributions. The simulations are for two MCSs, a tropical oceanic squall system observed during TOGA COARE (*Tropical Ocean and Global Atmosphere Coupled Ocean-Atmosphere Response Experiment*, which occurred over the Pacific Ocean warm pool from November 1992 to February 1993), and a midlatitude continental squall system observed during PRE-STORM (*Preliminary Regional Experiment for STORM-Central*, which occurred in Kansas and Oklahoma during May–June 1985). It should be noted again that spectral-bin microphysics does not discretize cloud droplets and drizzle droplet classes. Liquid drop class is discretized in mass (size) bins, but continuous from tiny cloud droplets to larger raindrops. Adapted from Tao, W.-K., Li, X.X., Khain, A., Matsui, T., Lang, S., Simpson, J., 2007. The role of atmospheric aerosol concentration on deep convective precipitation: cloud-resolving model simulations. *Journal of Geophysical Research* 112, D24S18. <http://dx.doi.org/10.1029/2007JD008728>.

clouds in a clean environment (low CCN concentration) produce fewer droplets, larger sizes developed due to greater condensational and collectional growth, leading to a better chance to form raindrops from cloud-drop coagulation as seen in Figure 4.

When CRM simulations are integrated over the mature stage of the deep convection, the effect of the elevated CCN concentration on rainfall ranges from rain suppression in the midlatitude continental squall-line case, to little effect in the Florida sea-breeze case, and to rain enhancement in the tropical squall-line case. These results suggest that model simulations of the whole life cycle of CPSs should be examined in order to assess the impact of aerosols on precipitation processes in various forms of CPSs under their embedded environments. These results will also show the complexity of aerosol–cloud–precipitation interactions within CPSs.

Another advantage of using CRM to study aerosol–precipitation interaction simulations is to identify the factors that determine how aerosol can exert an influence on rainfall. A scheme was proposed to classify the aerosol effects on clouds and cloud systems under different moist environments (Figure 6). It shows that if the air relative humidity is high (low), then the condensation gain (loss) is large and the condensation loss (gain) is low, that could lead to an increase (decrease) of precipitation. In addition, the CRM results show that the aerosol impact on precipitation depends on the types of CPSs. A decrease in the precipitation with an increase in aerosol concentration usually occurs for isolated cumulus

clouds, and cloud systems develop within a relatively dry environment and/or within large wind shear or stratocumulus clouds. The CRM simulations also found that the increase in CCN concentrations tends to suppress precipitation under strong wind shear but enhance precipitation under weak wind shear. On the other hand, an increase in precipitation with an increase in CCN concentrations often occurs for clouds forming in a moist environment, such as coastal zones or within cloud ensembles, tropical squall line.

Physical Processes of CCN Effect on Precipitation

The CRM results have been used to examine the physical processes that could lead to aerosol-induced changes in precipitation. In general, three mechanisms were proposed to explain the *enhancement of precipitation by changing (either increasing or decreasing) the aerosol concentration*. The first mechanism is the stronger updrafts/downdrafts resulting from enhanced latent heat release, when CCN suppress warm-rain formation, and thus retains more supercooled liquid water to be frozen above 0 °C isotherm levels. This effect could be termed as the *latent heat – dynamic effect* (see Figure 7). The CRM results found that for cases having enhanced precipitation with a high CCN concentration, the clouds are usually associated with stronger updrafts/downdrafts as well as stronger convergence in the boundary layer, which provides for a better chance to trigger the secondary convections and prolong the lifetime of the CPSs.

Figure 5 Time sequences of CRM estimated domain mean surface rainfall rate (mm h^{-1}) for (a) PRE-STORM, (b) TOGA COARE, and (c) CRYSTAL cases. The solid and dashed line is for clean and dirty condition, respectively. Adapted from Tao, W.-K., Li, X.X., Khain, A., Matsui, T., Lang, S., Simpson, J., 2007. The role of atmospheric aerosol concentration on deep convective precipitation: cloud-resolving model simulations. *Journal of Geophysical Research* 112, D24S18. <http://dx.doi.org/10.1029/2007JD008728>.

The second mechanism is the stronger evaporative cooling from a large number of concentrations of smaller raindrops under a high CCN-concentration condition. Rainfall evaporative cooling creates cold-air domes (domes?) under the stratiform rain area, denoted as cool pool. Enhanced evaporative cooling strengthens the near-surface cool pool. When interacting with the lower-level wind shear, colder cool pool induces the stronger low-level convergence, producing more vigorous convection that ultimately leads to enhanced surface precipitation. This positive feedback mechanism could be termed as *the cool pool effect*. It appears to be frequently occurring in the oceanic convective cases, in which the evaporative cooling in the lower troposphere is stronger for the polluted scenario compared to the clean scenario (Figure 8). Note that the stronger evaporative cooling occurs in the developing stage of the organized convective system.

The third mechanism is the CCN effect on ice microphysics. When CCN concentrations are elevated, cloud droplets tend to have lower collision efficiency due to smaller sizes. This reduces accretion and autoconversion, leading to less warm-rain process (Effect-A). Simultaneously, smaller cloud droplets, aloft in a mixed-phase zone, reduce collection efficiency with snow aggregates or ice crystals that reduce the riming process. If this process dominates, it may eventually reduce the cold-rain process (Effect-B). On the other hand, more supercooled cloud droplets aloft can enhance the riming process, if it does not lower collection efficiency (Effect-C). Thus, depending on changes in collection efficiency for the riming process, elevated CCN concentrations may lead to either less cold-rain (Effect-B) or a more cold-rain scenario (Effect-C). Regardless of the riming effect, more ice aloft due to enhanced supercooled cloud droplets can generally increase the amount of total ice-phased hydrometers, leading to a more cold-rain process (Effect-D). These processes can be termed as ice-microphysics effect (Figure 9). Total precipitation amount could be enhanced or reduced, depending on the

domination of these four microphysics paths in different types of CPSs.

CCN Effect on Convective Precipitation Using Nested Cloud/Regional-Scale Model

Regional-scale limited-area models (i.e., Regional Atmospheric Modeling System, Weather Research and Forecasting Model, and Pennsylvania State University–National Center for Atmospheric Research Mesoscale Model) with fine resolution (utilizing interactive nesting technique) have also been used to study the impact of aerosols on convective precipitation events associated with the Florida sea breeze, urban heat island effect, and tropical cyclone (TC)/hurricane. An advantage of this approach is that the model initial and lateral boundary conditions are provided by large-scale analyses with realistic meteorological fields, and model simulations can be conducted with realistic terrain and heterogeneous land-surface characteristics.

The regional-scale model has been used to examine the sensitivity tests of aerosol concentrations on a convective storm over the peninsula of Florida. The results found that the increase in CCN concentration led to convective invigoration and the formation of stronger secondary clouds. Simulations of rain events over the whole peninsula for this day showed significant invigoration of squall lines. There was an increase in precipitation rate and precipitation amount for a squall line that formed in the vicinity of the east coast of Florida. At the same time, continental CCN concentrations resulted in a 5% reduction in precipitation over the whole computational domain (containing a significant fraction of Florida) vs maritime values. On the other hand, the regional-scale model

results also showed that different combinations of CCN, GCCN, and IN result in different amounts and temporal patterns of cloud water/ice contents and rainfall. The high CCN reduces cumulative precipitation by 22% compared to low CCN. Also noted were, high-GCCN and IN enhanced surface precipitation for the first 6 h of integration due to the initial broadening of the cloud droplet spectra. However, the total (12-h integration) accumulated precipitation was greatest for the clean (low CCN, GCCN, and IN) case. This could be explained by a rapid wet deposition of GCCN for the first 6 h of integration.

High aerosol concentrations in urban environments could affect precipitation variability by providing an enhanced source of CCN. The regional model has been used to examine the sensitivity of urban-induced convective clouds over and downwind of St. Louis, MO. The results indicate that downwind convergence (dynamic processes) induced by urban land cover appears to be the dominant factor in determining whether or not moist convection actually develops downwind of St. Louis. Once moist convection is initiated, urban-enhanced aerosols play a major role in determining the microphysical and dynamical characteristics of convective storms, particularly when background aerosol concentrations are low (Figure 10). Complicated relationships and feedbacks between microphysical and dynamical processes obscure generalized understandings (i.e., a linear relationship) of urban-enhanced aerosol effects on precipitation.

Note that the regional-scale models could explicitly represent locally induced mesoscale dynamics (i.e., sea-breeze convergence and urban heat island convergence). This is important because model-simulated cool pool can interact with those circulations, introducing another level of dynamic

Figure 10 Time series of the accumulated volumetric precipitation in the downwind region expressed as a percentage of the RURAL-clean background simulation. RURAL-L stands for the simulation with clean CCN and GCCN background aerosol; CCN-L for the effects of the increase of CCN concentrations only over clean background concentration, GCCN-L for the effects of polluted GCCN concentrations only relative clean background concentration, URBAN-L stands for the effects of CCN and GCCN concentration relative to a clean background aerosol. Adapted from Van den Heever, S., Carrio, G.C., Cotton, W.R., DeMott, P.J., Prenni, A.J., 2006. Impacts of nucleating aerosol on Florida storms. Part I: mesoscale simulations. *Journal of Atmospheric Sciences* 63, 1752–1775.

complexity. The regional-scale model also showed that the response of convective rainfall to urban-enhanced aerosols becomes stronger when the background aerosol concentrations are low.

The regional-scale model has also been used to examine the impact of dust in the Saharan Air Layer (SAL) acting as CCN on the evolution of a TC. The results showed that the dust in the SAL as CCN could affect the simulated TC intensity by 22 hPa depending on CCN concentrations (Figure 11). The high CCN concentration could weaken the TC intensity. It can also affect eyewall development directly through the release of latent heat when activated and subsequent growth of cloud droplets and

indirectly through modulating rain band development. The development of rain bands tended to promote latent heat release away from the eyewall, block the surface inflow and enhance cold pools. However, results are no longer monotonic with increasing CCN. The impact of CCN on storm intensity was very sensitive to the background GCCN vertical profile and presumably other environmental factors. The regional-scale model was also used to investigate the potential impact of aerosols ingested into Katrina's circulation during its passage through the Gulf of Mexico on Hurricane Katrina's (2005) structure and intensity. The result was shown that continental aerosols invigorated convection largely at TC periphery, which led to its weakening prior to landfall. The minimum pressure increased by 15 hPa, and the maximum velocity decreased up to 15 m s^{-1} .

IN Effect on Precipitation Processes

Some types of aerosol can be transported by convective updrafts from PBL to middle- and upper-troposphere and can be served as IN. Only a few CRM-based studies have been identified for the effects of the IN on precipitation processes because of the limited understanding of ice formation and IN precursors (Pruppacher and Klett, 1997). *The CRM results indicated that the increase of IN concentration and, thus, heterogeneous ice nucleation would result in an enhancement in updraft due to latent heat release from added diffusive growth of increased ice crystals. Such an effect was also identified to enhance the homogeneous nucleation, i.e., to make CCN more effective in influencing the ice nucleation. Since the dominant mechanism in providing ice particles for cirrus anvil in the modeled case is still the homogeneous nucleation, the increase of IN concentration would lead to enlarged anvil coverage and increased stratiform precipitation. This finding*

Figure 11 Temporal evolutions of the minimum sea-level pressure MSLP and maximum surface wind for 'clean' (dotted line), 'polluted' (1000 cm^{-3} , thin solid line), and 'double' (2000 cm^{-3} , thick solid line). Adapted from Zhang, H., McFarquhar, G.M., Saleeby, S.M., Cotton, W.R., 2007. Impacts of Saharan dust as CCN on the evolution of an idealized tropical cyclone. *Geophysical Research Letters* 34, L14812. doi:10.1029/2007GL029876.

could imply that a linkage from IN concentration to anvil particle concentration, coverage, and therefore radiation effects. Their results could also have potential climate consequences through cloud-radiative effect.

Conclusion

Most of the CRM-based studies highlighted that high CCN concentrations could suppress initial warm-phase precipitation processes. However, high CCN concentrations could also enhance cold-phase precipitation processes depending on the surrounding environments potentially through interacting with latent heat, cool pool, and ice-microphysics effects. These simulation results show that the nonlinear interactions between aerosols and CPSs can occur. Indeed, fully understanding the interactive processes between aerosol, IN, and CPSs is still lacking at present due to limited observations. More case studies are required to further investigate the aerosol impact on different CPS events under different thermodynamic environments. In almost all CRM or regional-model studies, idealized, uniform, or single composite CCN concentrations were employed in the CRM simulations, and IN concentrations were not linked to the aerosol concentrations. A horizontally uniform distribution of CCN was also used in the regional-scale-modeling studies. A nonhomogeneous CCN distribution, consistent with the nonhomogeneous initial meteorological conditions, will be required to assess aerosol–precipitation interactions using regional-scale models in the future. In addition to IN and GCCN, the chemistry of CCN needs to be considered in future modeling of aerosol–precipitation interactions.

In addition, many CRM studies did not often compare model results with observed cloud structures, organization, radar reflectivity, and rainfall. It may require major field campaigns to gather the data necessary to both initialize and validate the models in terms of meteorological, cloud–precipitation, and aerosol parameters using *in situ* cloud property observations, radar, lidar, and microwave remote-sensing data. Although CRM-simulated results can provide valuable quantitative estimates of the microphysics effects of aerosols, CRMs can only simulate clouds and cloud systems typically over a relatively small domain, which does not feedback to general circulations. Close collaboration between the global and CRM communities is needed in order to expand the CRM results to a regional and global perspective.

CRMs together with observations should be a promising approach for studying the physical processes associated with aerosol–cloud–precipitation interactions. Modern CRMs operate with realistic, albeit not complete, microphysical parameterizations and simulate the evolution, structure, and life cycles of CPSs. Because of the range of scales resolved by modern CRMs, high-resolution observations from space-based remote sensing is becoming an ever more necessary part of the model validation through the state-of-art multiinstrument satellite simulators (Matsui et al., 2009).

Large-Eddy Simulation

C-H Moeng and PP Sullivan, National Center for Atmospheric Research, Boulder, CO, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Large-eddy simulation (LES) is a numerical technique for integrating spatially filtered equations of motion that describe high-Reynolds number time-evolving, three-dimensional turbulence. The spatial filtering cuts off the high frequency or small-scale part of the turbulence spectrum. Virtual turbulence generated by LES has been shown to be a surrogate for measurements of turbulent flow fields. LES is widely used for turbulence research and for applications. This article describes the LES technique, and reviews its contributions to and use in atmospheric sciences.

Introduction

Turbulence consists of a three-dimensional chaotic motion that spans a wide range of scales of motion, which increases with the Reynolds number (*see Turbulence and Mixing: Overview*). A numerical integration of the full (unfiltered) equations (i.e., the Navier–Stokes equations) that explicitly calculates all scales of turbulent motion is known as direct numerical simulation (DNS). However, DNS can simulate only low-to-medium Reynolds-number turbulence (where the range of scales is not very broad) with today's computer power. Low-to-medium Reynolds number flows are typical of wind tunnel laboratory experiments. The largest DNS performed today uses $\sim 10^{10}$ grid points, which is still insufficient to simulate turbulence with a very wide range of scales. As an example, consider the atmospheric planetary boundary layer (PBL). The largest turbulent eddies in the PBL are on the order of kilometers and the smallest on the order of millimeters; the entire scale range spans more than six orders of magnitude. To numerically integrate the full Navier–Stokes equations for a turbulent PBL requires at least 10^{18} numerical grid points (i.e., 10^6 in all three directions). This is far beyond today's computing capacity or that in the foreseeable future.

Given this limitation, only a portion of the scale range can be explicitly resolved. The obvious choice is to resolve just the most important scales of the flow of interest and approximate the other scales. This is the philosophy behind large-eddy simulation (LES). For PBL turbulence, as an example, the most important scales (for most meteorological applications) are large eddies which contain most of the turbulent kinetic energy (TKE) (thus called energy-containing eddies) and are responsible for the majority of the turbulent transport. A simulation that explicitly calculates (or resolves) large eddies while approximately representing the effects of smaller ones is LES (Wyngaard, 1984, 2010). As the grid resolution of LES becomes finer, a wider range of turbulent eddies is resolved, less are parameterized, and LES-generated flows become more representative of the entire flow field. LES is a compromise between DNS (in which all turbulent fluctuations are resolved) and traditional Reynolds-averaging approach (in which all turbulent fluctuations are parameterized and only ensemble-averaged statistics are calculated).

The LES technique was developed by Jim Deardorff at the National Center for Atmospheric Research in the late 1960s.

His first LES calculation was performed using a computer that allowed for only $32 \times 32 \times 32$ (32 768) grid points. On today's machines, calculations with 10^6 – 10^7 grid points are a common practice and 10^9 – 10^{10} computations are possible on massively parallel machines. As computer power increases, the LES numerical technique will have a much broader application and more accurate solutions. LES has been developed and used extensively also by the engineering fluid dynamics community, but in this article we restrict our description to LESs of atmospheric flows, with an emphasis on the PBL. Most LES research by the PBL community focuses on applications that include buoyancy, rotation, rough surface, ocean waves, canopy, entrainment, radiation, and/or condensation.

The LES Technique

Governing Equations and Filtering Procedures

The Navier–Stokes equations for an incompressible fluid are

$$\frac{\partial u_i}{\partial t} = -\frac{\partial u_i u_j}{\partial x_j} + X_i - \frac{1}{\rho} \frac{\partial p}{\partial x_i} + \nu \frac{\partial^2 u_i}{\partial x_j^2} \quad [1]$$

where the velocity field u_i satisfies the continuity equations

$$\frac{\partial u_i}{\partial x_i} = 0. \quad [2]$$

In eqns [1] and [2], u_i are flow velocities in the three spatial directions, i.e., $i = 1$ and 2 for the horizontal directions and $i = 3$ for the vertical direction, X_i are the i th-component of body forces, ρ is the air density, p is the pressure fluctuation, ν is the kinematic viscosity of the fluid, t is time, and x_i are the spatial coordinates. For PBL applications, the major body forces are gravity and Coriolis forces (*see Dynamical Meteorology: Coriolis Force*) and hence $X_i = g_i \theta / T_0 - f \epsilon_{ij3} u_j$, where the gravitational acceleration g_i is nonzero only in the x_3 (or z) direction, θ is the virtual potential temperature, T_0 is the temperature of some reference state, and f is the Coriolis parameter. The body force X_i is obtained by expanding eqn [1] over a reference state of hydrostatic equilibrium and also using the Boussinesq approximation (*see Dynamical Meteorology: Primitive Equations*). A numerical integration of eqns [1] and [2] is called DNS. For LES the governing eqns [1] and [2] need to be spatially filtered.

Spatially filtered Navier–Stokes equations are derived by decomposing all dependent variables, for example the velocity field u_i , into $u_i = \tilde{u}_i - u_i''$ where $\tilde{u}_i$ is the filter-scale component and u_i'' is the subgrid scale (SGS) (or subfilter). The filter-scale or resolved-scale variable is defined as

$$\tilde{u}_i(x_i) = \iiint_{\text{volume}} u_i(x'_i) G(x_i - x'_i) dx'_i \quad [3]$$

where G is a three-dimensional (low-pass) filter function (typically, a Gaussian, top-hat, or sharp-wave-cutoff filter). A turbulent flow field obtained from a point sensor illustrates the filtering and decomposition process. In Figure 1, the red curve denotes the time varying total flow field. Application of the filter operator shown in eqn [3] to the total flow field yields a smoother field called the filter scale (or resolved scale) as indicated by the blue curve. The difference between the total and resolved-scale components is the subfilter scale or SGS, shown by the green curve. The SGS component is much smaller in magnitude and is of much higher frequency, compared to the resolved-scale component.

Applying the filtering procedure, term-by-term, to eqn [1] leads to the equations that govern large (resolved-scale) eddies:

$$\frac{\partial \tilde{u}_i}{\partial t} = -\frac{\partial \tilde{u}_i \tilde{u}_j}{\partial x_j} - \frac{\partial \tau_{ij}}{\partial x_j} + \frac{g_i}{T_0} \tilde{\theta} - f \varepsilon_{ij3} \tilde{u}_j - \frac{1}{\rho_0} \frac{\partial \tilde{p}}{\partial x_i} + \nu \frac{\partial^2 \tilde{u}_i}{\partial x_j^2}, \quad [4]$$

where the SGS stress is defined as $\tau_{ij} = \tilde{u}_i \tilde{u}_j - \tilde{u}_i \tilde{u}_j$. For geophysical turbulence, the last term (molecular viscosity) is negligibly small compared to the other terms and hence can be ignored.

So far in deriving eqn [4] for LES calculations, no approximations have been made. However, to solve eqn [4] we need an SGS model to describe the SGS stress τ_{ij} .

Figure 1 A sketch illustrating the filtering and decomposition procedure. The red curve shows the time evolution of a turbulent flow field obtained from a point sensor. Applying the filtering procedure yields its filter-scale field (blue curve) and subfilter-scale (or SGS) field (green curve).

Subgrid-Scale (SGS) Models

An SGS model relates the SGS stress (or SGS fluxes) to resolved-scale variables, allowing eqn [4] to be integrated. This is a closure problem. The closure assumption made in an SGS model creates the only uncertainty – other than numerical errors – to LES-generated turbulent flows. This uncertainty may become severe in regions where small eddies are dominant (or play an important role), for example near a rough-wall boundary and perhaps in the entrainment zone of the PBL. Nevertheless, in regions where large turbulent eddies play the major role, LES-generated flows (and their derived statistics such as variances and fluxes) have been shown to be insensitive to the SGS model. This is true in the bulk of the PBL where small turbulent eddies act mainly as passive motions, passing energy downscale toward dissipation. This is a turbulence process known as the energy cascade. Thus, a simple SGS model that dissipates energy properly is usually sufficient to represent the net effect of small eddies – for most meteorological applications – if the LES grid resolution is properly chosen.

The most widely used SGS models for the PBL are the Smagorinsky–Lilly (S–L) and Deardorff’s TKE models. They are similar in that both are based on SGS TKE budgets and both relate SGS stresses to resolved-scale strain tensors as

$$\tau_{ij} = -2K_M S_{ij} \quad [5]$$

where the strain tensor is $S_{ij} = (\partial \tilde{u}_i / \partial x_j + \partial \tilde{u}_j / \partial x_i) / 2$. SGS heat fluxes are similarly related to local gradients of the resolved temperature field as

$$\tau_{\theta i} = -K_H \frac{\partial \tilde{\theta}}{\partial x_i} \quad [6]$$

The S–L model

Without the buoyancy effect the SGS eddy viscosity K_M and diffusivity K_H are expressed as

$$K_M = (c_S \Delta_S)^2 S, \quad [7]$$

and

$$K_H = \frac{K_M}{P_r} \quad [8]$$

where c_S is the Smagorinsky constant, Δ_S is a filtered length scale often taken to be proportional to the grid size, S is the magnitude of the strain tensor, $S = (2 S_{ij} S_{ij})^{1/2}$, and P_r is the SGS Prandtl number. One of the most important features of the S–L model is that the SGS fluxes are nonlinear functions of the resolved strain rate, a crucial difference from the viscous (molecular) stress–strain relationship. For PBL applications, the Smagorinsky constant c_S is often set to 0.18–0.25 and the SGS Prandtl number to $\sim 1/3$ to satisfy Kolmogorov inertial-subrange theory.

To include the buoyancy effect, the K_M expression in the original Smagorinsky model is modified to depend on local Richardson number R_i (the ratio of buoyancy to shear production terms of the TKE budget),

$$K_M = (c_S \Delta_S)^2 S \left(1 - \frac{R_i}{R_{ic}} \right)^n \quad [9]$$

where R_{ic} is the critical Richardson number often set between 0.2 and 0.4, and $n = 1/2$ is often used. When the local Richardson number reaches the critical value, turbulence within that grid cell vanishes and the eddy viscosity is shut off.

The Deardorff TKE model

Deardorff extended the S–L eddy viscosity model to include the full SGS TKE e :

$$\frac{\partial e}{\partial t} = -\frac{\partial \tilde{u}_j e}{\partial x_j} - \frac{\partial (\tilde{u}_j' e + \tilde{u}_j' p'')}{\partial x_j} - \tilde{u}_i' \tilde{u}_j' \frac{\partial \tilde{u}_i}{\partial x_j} + \frac{g}{T_0} \tilde{u}'' \theta'' - \varepsilon \quad [10]$$

and then relates K_M and K_H to SGS TKE as

$$K_M = c_K l \sqrt{e} \quad [11]$$

and

$$K_H = [1 + (2l/\Delta_S)] K_M \quad [12]$$

where c_K is a diffusion coefficient to be determined and l is another SGS length scale, taken as the minimum of the stability-corrected scale and the grid scale:

$$l = \min[0.76 \sqrt{e/N^2}; \Delta_S] \quad [13]$$

where $N = \sqrt{(g/T_0)(\partial\theta/\partial z)}$ is the Brunt–Vaisala frequency.

The terms on the right-hand side of eqn [10] represent, in order, advection of SGS TKE by the resolved-scale motion, turbulence and pressure transports, local shear production (i.e., nonlinear scrambling), local buoyancy production or consumption, and molecular dissipation. In solving eqn [10], the transport term is usually approximated as

$$\tilde{u}_j' e + \tilde{u}_j' p'' = -2K_M \frac{\partial e}{\partial x_j} \quad [14]$$

and the molecular dissipation rate as

$$\varepsilon = c_e e^{3/2} / l \quad [15]$$

where c_e is a dissipation coefficient.

Under the assumption that all SGS motions lie within the inertial subrange, the SGS parameters c_K and c_e can be derived assuming that the SGS motions are isotropic and the energy spectrum has a $-5/3$ spectral slope (Moeng and Wyngaard, 1988). Commonly used values for PBL applications are $c_K \sim 0.10$, and $c_e \sim 0.19 + 0.74 l/\Delta_S$. With these model parameters, LESs are, in a way, forced – in an ensemble-mean sense – to drain energy at a rate sufficient to produce a $-5/3$ spectral slope near the filter cutoff scale.

These two SGS models are closely related. The S–L model can be derived by keeping just the last three terms on the right-hand side in eqn [10]. The SGS constants of the two models are related as $c_S^4 = c_K^3/c_e$ (if the stability correction of the SGS length scale is neglected).

Deficiency of the eddy-viscosity SGS models

The above SGS models are based on ensemble average concepts but are used inside of LES on an instantaneous basis, i.e., to represent SGS effects at every grid point and at every time step. Laboratory studies and DNS provide evidence that small-scale turbulent motions are anisotropic and intermittent and that locally the energy transfer can either be forward scatter

(from large to small scales) or backscatter (from small to large scales), which causes deviations from the equilibrium $-5/3$ law. Eddy-viscosity SGS models also assume that SGS stresses and strains are perfectly aligned (eqn [5]), and hence the local dissipation rate $\varepsilon = -\tau_{ij} S_{ij}$ is always positive thus preventing backscatter of energy. These deficiencies of eddy-viscosity models have motivated continued development of new SGS models, including (1) stochastic models where a random field is imposed at the SGS level thus permitting a backscatter of energy, (2) dynamic models where the Smagorinsky coefficient is dynamically predicted using a resolved field filtered at two different scales, and (3) velocity estimation models that attempt to model the SGS velocity fluctuations u_i' instead of SGS stresses τ_{ij} .

The deficiency of the S–L and Deardorff SGS models is most evident in the surface layer of the PBL. Based on a large body of measurements and scaling arguments, the vertical gradients of the mean fields usually obey Monin–Obukhov (M–O) similarity theory (see **Boundary Layer (Atmospheric) and Air Pollution: Surface Layer**). However, LESs using the S–L or Deardorff SGS model fail to reproduce the vertical profiles of the mean fields predicted by M–O theory, particularly for shear-driven and stable PBLs. One reason for this shortcoming is that near the surface, small eddies dominate so that almost all of the turbulent eddies are SGS in LES; few motions are actually resolved. This deficiency has been improved somewhat using SGS models that include either a backscatter effect or a contribution from the mean shear near the surface (Sullivan et al., 1994).

Numerical Setup, Methods, and Boundary Conditions

The choice of LES grid and domain size depends on the physical flow of interest and the computer capability. LES differs from other meteorological models in that its resolved-scale (or grid-scale) turbulent motion has about the same characteristic scale in all three directions, and hence requires a grid mesh that is close to isotropic. Most computers today can easily perform an LES of about $100 \times 100 \times 100$ grid points. From these grid points, an LES domain is then chosen to resolve several largest (dominant) turbulent eddies and at the same time resolve eddies as small as possible into the inertial-subrange scales. For example, for a convective PBL with 1 km depth, a $5 \text{ km} \times 5 \text{ km} \times 2 \text{ km}$ domain of LES with $100 \times 100 \times 100$ grid points would cover 3–5 large dominant eddies in each horizontal direction and at the same time resolve small eddies down to about $100 \text{ m} \times 100 \text{ m} \times 40 \text{ m}$ in size assuming model resolution is twice the grid size. For the stable PBL where dominant eddies are smaller, a smaller domain (and consequently a finer grid) is preferred.

Numerical truncation errors and specification of boundary conditions add uncertainties to all numerical models including LES. Most PBL-LES codes use finite difference methods in all three directions to compute derivatives, although some LESs employ a spectral (Fourier) representation in x – y planes taking advantage of the horizontally homogeneous nature of the PBL and computational efficiency of using fast Fourier transformation. Sharp gradients in flow variables can exist at the top of the PBL because of the presence of a strong, stably stratified overlying layer, which leads to oscillations (dispersion errors)

when finite differencing methods are used. To overcome this flaw, sign preserving (monotone) schemes are often used for scalar transport to maintain physical realizability – at the expense of introducing more numerical diffusion (see **Numerical Models: Methods**).

The surface boundary condition in LES uses M–O similarity theory to relate surface fluxes to resolved-scale variables at the first grid level – at every grid point. Note that for PBL applications, LES cannot possibly resolve the viscous layer, which is less than a centimeter above the surface. The lowest grid level of a PBL-LES lies in the inertial sublayer, which is referred to as the surface layer. The primary empirical input parameter in M–O theory is the surface roughness height, which varies from less than 0.0001 m for a smooth sea to more than 0.1 m for heavily wooded terrain. This rough-wall boundary condition is different from the smooth-wall condition in engineering flows. Caution should be used, however, because M–O theory describes ensemble-mean flux-gradient relationships in the surface layer (see **Boundary Layer (Atmospheric) and Air Pollution: Surface Layer**) and may not apply well at the local LES grid scale. This problem becomes more acute when the LES horizontal grid size is comparable to or smaller than the height of the first grid level.

The upper boundary of a typical LES domain is usually set to be well above the PBL top to avoid influences of boundary conditions on simulated PBL flows. At the top of the domain, turbulence is negligible and a no-stress condition is applied. Because turbulent motions in the PBL may excite gravity waves in the stably stratified inversion layer, a mechanism for allowing gravity waves to escape at the top of the domain is often applied. This includes applying a radiation condition or adding a wave-absorbing sponge layer at the top of the model domain.

For lateral boundary conditions, almost all PBL LESs use periodic boundary conditions because there is no adequate theory to define chaotic flow fields at an open boundary. However, periodic boundary conditions are clearly inappropriate for horizontally inhomogeneous cases, particularly for PBLs over complex terrain or under severe weather conditions. Recently, researchers have been using the nesting technique to avoid the use of periodic boundary conditions. We will get back to this issue later in **Weather Model Nesting**.

Visualization of LES-Generated Flows

The solution of eqn [4] consists of three-dimensional, time-evolving, chaotic flow fields. An example of such a flow field is shown in **Figure 2** where the vertical velocity of an LES solution of a free convective PBL (using $512 \times 512 \times 512$ grid points) is presented. The total domain of the LES is 5 km $\times$ 5 km in horizontal and 2 km in the vertical. The horizontal view shows a spokelike, irregular polygonal structure near the surface, similar to those observed in Rayleigh–Bernard convection experiments. This spokelike feature is most evident in the free convective PBL where there is no mean wind. Intersections between polygons are local horizontal convergence regions and hence are sites to form strong updrafts (purple colors).

Strong updrafts can be seen from the two vertical plan views. These updrafts carry warm surface air and that is how turbulence can effectively transport heat (and other species

Figure 2 Contours of vertical-velocity field from an LES of the free convective PBL, shown on a horizontal plane near the surface and also on two vertical cross sections. The purple color indicates strong updrafts and red for strong downdrafts. The total domain is 5 km in both horizontal directions and 2 km in the vertical.

coming from the surface) upward. Updrafts are more intense and occupy a narrower area than downdrafts; this is known as a positively skewed vertical-velocity field, a unique feature of buoyancy-driven turbulence. Strong updrafts penetrate into the capping inversion and in the process engulf wisps of warm inversion air into the PBL. These wisps of air are subsequently entrained and mixed into the PBL. This penetration-leads-to-entrainment is a phenomenon that has been documented with radar and lidar observations and convection tank experiments (see **Boundary Layer (Atmospheric) and Air Pollution: Convective Boundary Layer**).

Turbulent structures are quite different in a stably stratified (or night-time) PBL. **Figure 3** shows the vertical-velocity field from an LES of a stable PBL. In the stable PBL, buoyancy consumes TKE that leads to much weaker turbulence compared

Figure 3 Contours of the vertical-velocity field from an LES of a stably stratified PBL, shown on a horizontal plane near the surface and also on two vertical cross sections. The purple color indicates strong updrafts and red for strong downdrafts. The total domain is 400 m in all three directions.

to the convective PBL. There is no spokelike structure and no strong updrafts. There are numerous small-scale interacting turbulent patches. (Field measurements show that the dominant turbulent eddy size in a typical stable PBL is on the order of several tens of meters. So for this simulation, the total domain is set to 400 m in all three directions using $200 \times 200 \times 200$ grid points.)

Statistics Derived from LES Flows

Instantaneous flow fields from LESs are chaotic, so it is their collective effects (or statistics) like variances or fluxes that are useful for applications. Moment statistics can be readily calculated from 3D LES data by correlating the local fluctuations among variables and averaging them over space and/or time. Then the vertical profiles or distributions of these statistics can be systematically documented for various PBL regimes generated under various large-scale conditions. For example, the TKE budgets calculated from LESs (Moeng and Sullivan, 1994) show differences between the shear and buoyancy-driven PBL regimes (Figure 4). In a shear-driven PBL, shear production nearly balances molecular dissipation with all other terms remaining small, while in the convective PBL, the TKE budget is dominated not only by the buoyancy production and molecular dissipation but also by the turbulent and pressure transports; these features are consistent with field observations and laboratory experiments.

A unique feature of LES is the ability to obtain pressure statistics. Pressure fluctuations are difficult, if not impossible, to measure in the field, yet they play an important role in determining moment statistics, such as pressure transport in the TKE budget and the return-to-isotropy behavior for velocity variances. The LES-generated pressure field, which remains to be verified from observation when available, provides a unique tool to estimate important pressure-related statistics.

One should be cautious in using statistics constructed from LES flows, however. Some statistics, especially higher moments, may be sensitive to the LES grid resolution, domain size, and SGS models. A necessary but not sufficient rule of thumb is to

accept or consider only the statistics that are insensitive to the LES grid resolution or SGS modeling.

Applications to Atmospheric Turbulence

Significant Accomplishments

LES has become a prominent research tool in advancing our understanding of the structure and physics of PBL turbulence. Before Deardorff's first LES calculations in the early 1970s, researchers believed that the proper velocity and length scales for PBL statistics were the friction velocity u_* and the length scale u_*/f , where f is the Coriolis parameter. Based on his LES calculations, Deardorff discovered that turbulence statistics in the convective PBL are better described by the convective velocity scale $w^* = [(g/T_0)z_i\overline{w\theta_0}]^{1/3}$ and the PBL depth z_i , where $\overline{w\theta_0}$ is the surface buoyancy flux (Deardorff, 1972). (Note that the overbar here denotes ensemble averages, which can be calculated as spatial and time averages from LES-generated flows.) This new finding, now known as mixed-layer scaling, makes it possible to collapse observed data collected from convective PBLs under various environments to form universal vertical profiles. For example, measurements of vertical flux of TKE $\overline{wE}$ and vertical-velocity variance $\overline{w^2}$ from research aircrafts at various heights, for various surface heat fluxes, form universal profiles only when these statistics are normalized by w^3 and w^2 , respectively, and also when they are shown as functions of the normalized height z/z_i (Figure 5, from Lenschow et al., 1980) (see **Boundary Layer (Atmospheric) and Air Pollution: Convective Boundary Layer**).

LES also has provided a revolutionary discovery about plume dispersion in the convective PBL. The release of a tracer from an elevated source within an LES-generated convective PBL shows that the maximum mean concentration in the plume at first descends until the plume intercepts the ground before it rises (Figure 6). The descent of the elevated plume maximum is due to the greater areal coverage of downdrafts, i.e., the positively skewed vertical-velocity field (Lamb, 1978). This finding, also observed at about the same time in the Willis and Deardorff tank experiments, has an important application to air pollution; the result can be used to predict the location and magnitude of the maximum surface concentration of emissions downstream. It provided the basis for the revision of short-range dispersion models in the 1980s (see **Turbulence and Mixing: Turbulent Diffusion**).

Another breakthrough from LES is the discovery of the asymmetry of turbulent diffusion from area sources at the surface and top of the convective PBL. Any passive, conservative scalar can be linearly decomposed into two conceptual scalar fields: top-down (which is emitted at the PBL top and has 0 flux at the surface) and bottom-up (which is emitted at the surface and has 0 flux at the PBL top). Under quasi-steady state, the fluxes of the top-down and bottom-up scalars are both linear in height and hence, after normalization by their respective boundary flux, are symmetric about the mid-PBL. LES shows that the mean gradients of the top-down and bottom-up concentrations, after normalization by w^* , z_i and the appropriate boundary flux, are *not* symmetric about the mid-PBL (Wyngaard and Brost, 1984). While the top-down gradient function remains positive throughout the whole PBL, the

bottom-up mean gradient is positive in the lower half of the PBL but becomes negative in the top half (Moeng and Wyngaard, 1984). The negative gradient in bottom-up scalar indicates the counter-gradient transport feature, where flux and mean concentration gradient have the same sign. This asymmetric feature of the gradient functions results in different top-down and bottom-up eddy diffusivities, where the latter becomes ill-defined in the mid-PBL. Thus, in the convective PBL, a scalar emitted from the surface diffuses differently from one emitted from the top.

One of the major contributions of LES to the meteorological community is the development or calibration of PBL parameterizations, referred to as PBL models (see **Boundary Layer (Atmospheric) and Air Pollution: Modeling and Parameterization**) for climate and weather forecasting models. Various PBL parameterizations have been proposed but few of them have been evaluated or verified because field observations are often incomplete for this application. LES solutions have been used as valuable datasets to examine many closure assumptions in existing PBL schemes. This includes assumptions made

in second-order closure modeling; mass flux and entrainment/detrainment closures for mass flux modeling; entrainment-rate closure assumptions in mixed-layer modeling; and counter-gradient effects in eddy-diffusivity models. Recently, LES has been extended to study not just parameterizations of PBL turbulence but all SGS motions in cloud-resolving (cloud-system-resolving) models.

Recent LES Research for Atmospheric Science

Earlier LES work focused mainly on idealized cloud-free, flat-terrain convective PBL. This flow regime is most suited to LES because of the presence of large thermal plumes with no other complicated physical processes (like radiation and latent heating) involved. In recent years, however, LES has been expanded to study more complicated and difficult PBL regimes that are relevant to climate and severe weather predictions, or more recently wind-energy applications. We list several topics below.

Stratocumulus-Topped PBLs

One climatologically important PBL regime is the stratocumulus-topped PBL where its extensive cloud cover can significantly alter the solar radiation input to the Earth's surface. For this PBL regime, LES needs to include effects of latent heating (i.e., phase change of water substance) and radiation processes, which unfortunately introduce more uncertainties into LES. In particular, the entrainment process of this PBL regime is very difficult to simulate because it depends sensitively on the SGS model and numerical schemes (Stevens et al., 2005). Many LES practitioners working on this topic have been involved in GCSS (GEWEX Cloud-System Study) Boundary Layer Cloud Working Group, with the goal of using LES as database to improve representations of stratocumulus clouds in climate and weather prediction models.

Weather model nesting

Limited by computer power, traditional atmospheric models have been used to perform single-scale simulations. For example, weather models simulate only weather-scale motions of several tens of kilometers in size, while LES resolves just large turbulent eddies of several hundreds of meters in size. The nonresolved part of motions in traditional weather models are either prescribed or roughly parameterized. This is clearly not suitable for applications where weather and turbulent motions strongly overlap or interact. One way to deal with this problem is the development of multiple-scale modeling that nests a turbulence-resolving model (i.e., LES) inside a weather prediction model. The outer domains with coarser grid resolutions resolve weather-scale systems, while the inner domains consist of a fine-grid LES to resolve turbulent motion. With two-way nesting, scale interactions of weather and turbulence motions are allowed.

The nesting technique may also solve the periodic-boundary-condition problem. With nesting, the lateral boundary conditions of LES are provided by their adjacent outer-domain flow fields. Thus no periodic boundary condition is imposed; such LES can be applied to horizontally

inhomogeneous, nonperiodic conditions. Built on community weather models, notably the Weather Research and Forecasting (WRF) model, this type of multiple-scale modeling has shown promising results when applied to idealized or uniform-surface cases (Zhu et al., 2010). It remains a challenge when applied to complex terrain or severe weather situations (see **Boundary Layer (Atmospheric) and Air Pollution: Complex Terrain**). (For further reading see the WRF website at <http://www.wrf-model.org/index.php>.)

Deep cloud systems

With massive parallel computing, LES is no longer limited to idealized PBL applications. For example, as part of the research funded by the NSF Center for Multiscale Modeling for Atmospheric Processes, a very large-domain LES, covering an area of about $205 \text{ km} \times 205 \text{ km}$ in the horizontal and about 27 km in the vertical, was performed to simulate a tropical deep convective system (Khairoutdinov et al., 2009). It used $2048 \times 2048 \times 256$ (about 10^9) grid points and ran on thousands of processors. This LES resolves a broad range of scales that includes mesoscale organization, gravity waves, deep and shallow clouds, all the way down to energy-containing turbulence eddies. This is another kind of multiple-scale modeling but it does not use the nesting approach, and therefore is more accurate. However, it is done at the expense of huge computer resources; a 24-h simulation of this LES took about 400 000 h on IBM's BlueGene/L supercomputer.

A satellite view of the simulated cloud field shown in **Figure 7** (adopted from Khairoutdinov et al., 2009) reveals a detailed structure of the deep convective system. It shows mesoscale organization, deep and shallow clouds (bright white color), thin cirrus clouds (light blue), and random turbulent motions. This computationally expensive LES is now used as a benchmark to study how large clouds interact with small clouds and turbulence. It is also used to develop SGS parameterizations for cloud-resolving models (Moeng et al., 2010). (For this LES see www.cmmmap.org.)

Large-domain LES is also used to simulate hurricane and midlatitude squall line systems.

Marine boundary layers with resolved waves

There is a clear impetus for using LES to attack increasingly complex flows for a variety of applications. Air-sea interaction and the coupling between winds and currents with surface gravity (water) waves is an example where LES has provided new information about turbulent flow dynamics and has also guided the interpretation of data collected in field campaigns.

To simulate atmospheric turbulence above a three-dimensional time-dependent surface wave field, the LES governing equations are written in a transformed wave-following coordinate system (Sullivan and McWilliams, 2010). The new complexity introduced here is that the gridlines of the mesh translate vertically adapting to the surface movement. The LES system of equations is augmented by an additional equation governing the grid movement. LES of the atmospheric marine boundary layer with varying stratification illustrate the importance of wind-wave directionality and so-called 'wave age,' i.e., the ratio of a reference wind speed and a characteristic

Figure 7 Visualization of simulated cloud scene over an area of about $205 \text{ km} \times 205 \text{ km}$ generated from the large-domain LES. The image represents visible albedo estimated from the liquid and ice water paths. The cloud arcs around some of the deep clouds are shallow clouds lifted up by the gust fronts at the edges of spreading cold pools. White color indicates thick clouds, semitransparent gray-blue indicates thin cirrus clouds, and dark-blue color shows the cloud-free regions. Large-eddy simulation of maritime deep tropical convection. *Journal of Advances in Modeling Earth Systems* 1, Art # 15, 1–13.

wave speed in a surface wave height spectrum. Depending on wave age, the winds are slowed or accelerated by the action of the waves. The mean wind profile, turbulence variances, and vertical momentum flux are thus dependent on the nature of the wave field; the LES predicted dependence of vertical momentum flux on wave age is also found in observations. LES results with moving waves show important differences compared with rough-wall boundary layers and flow over stationary bumps. LES of upper ocean boundary (or mixed) layers also incorporates surface wave effects by including the Stokes drift associated with the wave field. The latter appears as a new forcing term in LES, a so-called vortex force, which is responsible for the generation of Langmuir circulations. Langmuir circulations are potent coherent structures that interact with background ocean turbulence to produce enhanced mixing and entrainment in the ocean boundary layer.

Observations of SGS variables

The basic assumptions used to derive SGS closure models and constants for LES, discussed previously, are often violated in actual LES implementations. Flow near rough boundaries, regions with stable stratification, and the addition of new dynamical processes, e.g., vegetation, hills, and clouds, modulate the background turbulence and introduce new time and length scales that are not accounted for in conventional SGS closures.

Recently, novel observations have been carried out in the atmospheric surface layer with the objective of measuring and quantifying the structures and statistics of SGS variables. The basic principle of the Horizontal Array Turbulence Studies (HATS) is to sample turbulent fields by orienting an array of point sensors, usually sonic anemometers, perpendicular to the main flow direction. Then by adopting Taylor's hypothesis in the streamwise direction, a 'horizontal plane of turbulence' can be constructed. A two-dimensional filter (in horizontal directions) is applied to the wind and temperature fields that mimic the filtering in LES codes. If a sufficient number of sensors are employed, then the fields can be double filtered to yield additional information about the coupling between resolved and SGS correlations. Further, if a vertically stacked array of sensors is used in the field (Figure 8) vertical derivatives of resolved and SGS variables can be acquired. HATS field campaigns have been carried out over flat rough surfaces, moving ocean waves, in a canopy of trees, and over snow. In these studies, the atmospheric stratification varies from unstable to neutral to stable. (For these field data, see <http://data.eol.ucar.edu/codiac/projs?SGS00>.)

The statistics of SGS variables, from the HATS experiments, are studied similar to their conventional ensemble average counterparts for means and Reynolds-averaged fluxes and

Figure 8 Twin horizontal arrays of sonic anemometers with 9 and 5 sensors displaced vertically.

variances. Analysis of SGS momentum and scalar fluxes from HATS (Sullivan et al., 2003) shows that the scale separation between the largest energy-containing eddies Λ and the filter scale Δ is a fundamental critical parameter. The variation of the SGS fluxes and variances for different filter widths, height above the surface, and atmospheric stratification collapse when plotted as a function of Λ/Δ . When the ratio Λ/Δ is large (>10) then the SGS variables are more isotropic and can be modeled using expressions described previously. In an intermediate range of scale separation ($1 < \Lambda/\Delta < 10$), the SGS fluxes become increasingly anisotropic, and more complex closures are required (Wyngaard, 2004). When $\Lambda/\Delta < 1$ then the resolved motions are small compared to the SGS and second-order closure modeling is appropriate. HATS datasets can be used to estimate the transfer of energy between the resolved and SGS field and viscous dissipation in eqn [10] as well as closure constants. The observations show that the Smagorinsky constant c_s in eqn [7], (or c_K in eqn [11]) is dramatically reduced near rough boundaries.

Future Challenges

In reality, the PBL is much more complicated than what has been simulated by LES so far. Much of the complication arises from the heterogeneous nature of the underlying surface. The earth's land surface is characterized by spatially varying patches, undulating terrain, and urban development, which can induce circulations that interact with, and hence change turbulence dynamics. Complex surface conditions in particular affect the very stable PBL where turbulence is no longer continuous but becomes intermittent in space and time (see **Boundary Layer (Atmospheric) and Air Pollution: Stably Stratified Boundary Layer**). The ability to simulate turbulence transition becomes crucial. Wave-current couplings and wave breaking also lead to complex air-sea interactions. All these complex surface conditions can significantly influence turbulent transport in many meteorological applications, such as air pollution, vegetation growth, cloud formation, and hurricane development.

LES is now being adapted to realistic PBL regimes embedded in multiscale meteorological flows. Including complexities, however, introduces additional uncertainties in LES solutions. It is important to examine and validate the fidelity of LES of complicated flows against observations. LES has also been used to study interactions of turbulence with cloud microphysics, biochemistry, and aerosols. Caution should be exercised in these applications since the interactions may depend critically on small-scale turbulent motions, which are SGS in LES.

Regional Prediction Models

BW Golding, Met Office, Exeter, UK

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Regional numerical weather prediction (NWP) models are used by many National Meteorological and Hydrological Services to forecast the detailed weather over their areas of responsibility for the next few days. Their main advantages are in achieving much higher resolution, with limited computer power, than is possible with a global model and in delivering forecasts more quickly and frequently. They require information from a global model to provide the forecast for the boundary of the regional domain. Advanced NWP centers use regional models with grid lengths ranging from 1 to 3 km.

Introduction

Numerical weather prediction (NWP) models are at the heart of the modern production of weather forecasts. They use the mathematical equations governing motion of a thin shell of gas on a rotating sphere, together with the equations describing changes of the state of water between vapor, liquid, and ice, and supplemented by additional computations to represent the effects of the sun's radiation, of clouds and of the turbulence generated by surface topography. In addition, the conditions at the bottom of the atmosphere must be specified. A constant temperature, obtained from recent observations, is usually specified over the oceans, but over land the evolution with time must be predicted using equations that describe the interaction between radiative heating or cooling and evaporation at the surface, and the heat and water content of the soil beneath, taking account of the effects of vegetation on these processes. The result is a comprehensive description of the state of the atmosphere and the earth's surface at regular intervals in space and time.

Regional prediction models are NWP models that predict the evolution of the atmosphere overlying a limited part of the earth's surface. Such models are used so that, with limited computer power, the atmosphere overlying this part of the earth's surface can be modeled with the highest possible resolution. For simplicity, we exclude variable resolution global NWP models, which are used by some weather services as an alternative method of achieving this aim. We also exclude those models designed for simulation rather than forecasting, since they are typically designed to focus on the study of particular processes or meteorological events, and cannot properly be termed prediction models. A key distinguishing feature of a prediction model is that it has a data assimilation component to specify the initial state.

Whereas global NWP models have boundaries only at the bottom and top of the atmosphere, a regional model has lateral boundaries at the edges of the region covered. Conditions at these boundaries may be held fixed, may be prescribed from another model covering a larger area, or may be interactive, passing information both from and to a model covering a larger area. The study of how to optimally specify the boundaries of regional models has been very important in their evolution, and has also led some scientists to abandon them in favor of variable resolution global models, as mentioned above.

Requirement

The need for regional models comes out of the requirements placed on National Weather Services (NWSs) for forecasts of high impact weather and for detailed forecasts that distinguish the weather forecast at different locations characteristic of the topographical variability of a country (**Figure 1**). Weather systems that can have high impact include thunderstorms and

Figure 1 Representation of land surface height in the UK convective scale model (heights in meters).

squall lines, both of which are typically less than 10 km across, and fog, which is often constrained by valleys, also of small size. For countries with coastal or mountainous regions, the local variations of importance to citizens also occur at very small scales: typically less than 10 km separating a headland from a bay or a mountain from a valley. These requirements place a strong pressure on the weather forecasting agencies to forecast at the finest possible resolution and, with a given amount of computer power, this can best be achieved using a regional model embedded in a coarser resolution global model, the latter being run either locally or often at a remote center. NWSs are also required to provide weather information for all parts of their country, so regional models are usually configured so as to encompass the whole of the country plus a border region where the forecast may be distorted by the boundary conditions. As a result of these two conflicting requirements, it is often the case that the highest resolution regional models are run by the smaller countries.

The requirements placed on NWP models are intimately bound up with progress toward using automated methods in the preparation of weather forecasts, and therefore match to a large degree the meteorological requirements of the weather forecasts themselves. The dominant driver for development of regional models has been the goal of Quantitative Precipitation Forecasting. While the capability of models to predict precipitation has steadily improved, it is only in recent years that even regional NWP models have been able to resolve the processes that are relevant to flood producing rainfall. Apart from rainfall, regional NWP models are also able to forecast all of the elements of a typical public weather forecast: temperature, wind, cloud, snow, hail, and fog. The skill of models varies with the location, the lead time and the variable of interest. For some variables, the raw model forecasts can be improved using automated algorithms based on either the recent historical performance (e.g., using model output statistics) or the conditions at the start of the forecast (e.g., using nowcasting techniques).

For longer lead times, the area of the globe that influences the local weather becomes larger, and so the distortions to the forecast due to the artificial boundary become more important. These distortions counteract the benefit of higher resolution. Since the forecasts become less accurate anyway at longer lead times, most regional models are only used for short range weather forecasting, up to about 2 days ahead. However, some recent advances in high-resolution modeling mean that these models can provide useful additional information at much longer ranges. This use of regional models is termed 'dynamic downscaling' to indicate that the information on the evolution of the atmosphere is all coming from the global model, but the regional model is computing the result of the large-scale weather systems interacting with the smaller scale local topography. It is also possible to estimate these interactions using 'diagnostic downscaling' methods, but they are only able to represent a very simplified set of interactions compared to those that can be represented by the NWP model.

Development

The first NWP models were all regional models due to lack of computer power and of observations to drive global models.

Indeed it was not until the late 1970s that the first global NWP models were introduced, although global atmospheric circulation models had been run for some time previously to support atmospheric research.

Since there were no global models to provide boundary conditions, early models had to use fixed boundary conditions. This resulted in a severe limitation on the lead time for which forecasts were useful, since the effects of these erroneous boundary conditions propagated rapidly into the forecast domain. The earliest models were balanced models, obtained using the quasigeostrophic approximation. This resulted in a pronounced simplification and allowed the powerful theory of quasigeostrophic flow dynamics to be used in designing them. The later move to the so-called primitive equations allowed more accurate representation of important processes, but considerably complicated the model structure, and especially the processes required to produce an initial state from which a realistic prediction could be made. After several years the main types of model split the equations so that the smooth evolution obtained with the balanced equations could be integrated cheaply using long time steps, while the fast motions could be integrated less precisely, but in such a way as to ensure the stability of the solution. Two techniques have been widely used for this, the so-called split-explicit and split semi-implicit methods. It was at this time, also, that modelers divided into those using atmospheric variables defined at grid points, and those using a Fourier decomposition of the distribution of the variable. The latter, termed the spectral method, has proved very valuable for global modeling, but few centers have adopted it for regional models.

An important issue for all limited area models was the method of specification of the boundary conditions. There are important mathematical constraints on this, arising from the atmospheric equations being solved. Important work in the 1970s demonstrated that the specification should be different at inflow boundaries from that at outflow boundaries, but that the assessment of the type of boundary should take account not just of the mean wind, but also of the speed of traveling pressure waves. The complexity of such solutions deterred operational modelers, who generally specified all available variables, and then controlled any resulting disturbance using diffusion. In the end, it was shown that specification of a mathematically correct set of conditions is not possible for the primitive equations. Following from this, research into more pragmatic methods resulted in the technique most widely used today, in which the boundary values are blended into the regional model across several rows of the grid, with decreasing weight toward the interior. This technique suppresses the generation of unrealistic small-scale gravity waves while ensuring that information on the scale of the forcing model is transferred into the interior of the regional model.

As computers became more powerful, there was pressure to extend the boundaries so as to enable realistic longer forecasts to be run. On the other hand, there was also a desire to use finer resolution grids so as to increase the detail in the area for which the forecast was being made. The almost universally adopted solution has been to use a coarse grid covering the whole globe to forecast for the longest lead times possible, and to nest inside it a fine grid regional model covering a domain surrounding the required forecast area.

In some cases, two nested models have been used to enable the finest possible resolution to be used over the immediate forecast area, without having too large a change in resolution at the boundaries. However, it is recognized that each boundary introduces distortions, so this is not generally favored.

Given the cost of high performance computers, an option increasingly being adopted is for countries to combine resources in running a shared global model from which each obtains boundary conditions for its own regional model run at whatever resolution the computer power they can afford will allow.

Although much used for experimental simulations, two-way nested models typically place too great restrictions on the forecasting process and so are not used in regional NWP. Apart from centers that use boundary conditions from another center, which obviously makes two-way nesting impossible, other objections include the need to run the models simultaneously and the need for the models to have the same specification. Typically, global models run after waiting several hours for data from around the world, whereas regional models can run more quickly using local data. The specification of a regional model may well be different for various reasons, including the fact that different numerical techniques work best over different domains, as well as to enable the model to focus on the atmospheric processes most important in the region of interest. Notwithstanding these drivers, there are considerable advantages in the 'seamless' approach to atmospheric modeling, in which multiple configurations of a single model are used for different domains and lead times. With this approach, the scientific expertise in atmospheric radiation processes, for instance, only needs to be applied once to develop a representation for the model, and it can then be used in all configurations, whether global or regional, short range or climate.

Recent development has focused on the so-called convective scale models, with grid lengths of about 1 or 2 km, in which convective storms are represented explicitly rather than being represented by a statistical average of their effects on the larger scale flow. While considerable success has been gained with regional models running at these scales, the theoretical foundation for their performance is much less well understood than for the coarser resolution models and this has undoubtedly slowed down the development of some aspects, particularly the fitting of the initial state to available observations.

While most global models and many regional models represent the vertical structure of the atmosphere using the hydrostatic approximation, which assumes vertical accelerations are small, an increasing number of centers are now using nonhydrostatic models. This is necessary for models that represent convective processes explicitly. The theoretical foundation for these models is significantly more complex than it is for hydrostatic models, and there is, as yet, no agreement on the best form of the equations to be used, some allowing the presence of sound waves, and others excluding them. As with the earlier move from quasigeostrophic to the primitive equations, the methods of treatment of the faster motions and slower motions also differ between models.

Looking to the future, there will undoubtedly continue to be a desire to move to even smaller grid models so as to capture more of the structure of convective storms and local weather systems. However, there are other aspects of the coarser

resolution global models that also have a claim on some of the computer power that will become available in the next few years.

Several weather services are already experimenting with ensembles of convective scale models to try to gain information on the level of certainty in the storm predictions. For the current generation of global models, ensembles are run by perturbing both the initial state of the forecast and the parameters of the forecast model to estimate the sensitivity of the forecast. Techniques have been developed to gain the maximum information about the sensitivity of forecasts of the main weather systems that use as few perturbed forecasts as possible. For a regional NWP model, the primary source of perturbation is likely to be in the weather systems crossing the boundaries from the global model. However, added to this will be the sensitivity of the local weather systems to local perturbation. These are initiated by different processes from the large-scale weather systems, so the perturbations will need to be optimized quite differently.

Another area of development in global models is to extend the processes represented in the models to include those that alter the composition of the atmosphere, including chemical interactions, and to incorporate a dynamic representation of the oceans in place of the fixed sea surface conditions. These developments are well advanced in the climate modeling community, who have coined the term 'earth system model' to describe such a combination of atmosphere, ocean, and land surface in a full interactive model. The benefits are particularly important in long climate forecasts because the ocean has modes of variability on timescales of years to decades. However, such coupling is also of importance for short range forecasting with regional models. Shallow seas respond much more quickly to solar heating than the deep ocean, and the resulting gradients of sea temperature can be stretched out by tidal currents around coasts. Emissions of gases and aerosols from cities and industries can have significant effects on cloud and fog formation. Heavy rain, channeled through rivers, provides an enhanced freshwater source to coastal waters, creating salinity gradients that drive ocean processes. All of these linkages require a coupled regional model for their proper representation.

The other area of very active development is the coupling of impact models to regional NWP models. Impact models may represent physical, biological, social, or economic processes, but the thing they have in common is that they convert the weather variables output by the NWP model into impacts that are of importance to society. With the recent advances in the resolution of regional NWP models, there are now many more impacts of the weather for which the weather forecasts have the precision required to attempt their direct prediction. A good example is flooding, for which forecasts used to rely almost exclusively on upstream river measurements. With the advent of convective scale precipitation forecasts, there is considerable interest in assessing their ability to drive flood forecasting models, especially for rapidly responding catchments that were excluded from previous forecasting approaches.

Examples

The regional NWP model used by the Met Office in the United Kingdom is a convective scale configuration of its general

purpose Unified Model, which is also used for global prediction and climate modeling. It is a nonhydrostatic, grid point model, with one-way boundary conditions provided from a global model with a 25 km grid. The domain is defined as a rectangle on a reprojection of the earth's surface obtained by rotating the poles so that the British Isles appear to be near the equator. The horizontal grid has a spacing of about 1.5 km covering the British Isles and a small surrounding area. This area is made as large as possible by using a stretched grid, which expands up to 4 km. In the vertical, there are currently 70 levels, which follow the shape of the land/sea surface at low levels, but which become flatter at higher levels, until they are surfaces of constant pressure at the top.

The model uses the nonhydrostatic, compressible equations of atmospheric flow in semi-implicit form, with the unbalanced motions integrated implicitly. Sophisticated submodels calculate the influence of clouds, solar and terrestrial radiation, surface vegetation, and turbulence. A full forecast up to 36 h ahead takes about 15 min on an IBM P7 supercomputer.

The initial state for each forecast is obtained by incorporating observations of surface and upper air conditions into the model. These observations are made at fixed times by NWSs, by ships at sea and by aircraft in flight. Together with the observations made by satellites they are exchanged between all of the world's weather services using a sophisticated global data network. The Met Office model uses a three-dimensional variational method for assimilating the observational information

into the model state. In addition, the model state is 'nudged' toward precomputed analyses of cloud and precipitation obtained from radar and satellite imagery, together with lightning fixes and surface cloud and precipitation observations. The aim of the assimilation process is to create an initial model state that evolves smoothly and accurately in the early part of the forecast, avoiding the so-called spin-up problem when the precipitation, for instance, may be deficient in the first few hours of forecast.

A 36 h forecast is produced every 3 h.

The main products from the model are charts of near surface temperature, wind and visibility, cloud amount and height, and precipitation amount, which are used as guidance by forecasters (Figure 2). However, the results are also used as the basis for generation of automated forecasts, which are now competitive with manually generated forecasts for many purposes.

COSMO (CONsortium for Small-scale MOdeling) is a regional model that has been developed by a consortium of European weather services and is implemented in several different configurations in member countries (Figure 3). The German Weather Service uses a convective scale configuration, called COSMO-DE (CONsortium for Small-scale MOdeling-DEutsche), with a horizontal grid spacing of about 2.8 km. Trials of this configuration showed particular skill in the prediction of severe rainfall events leading to floods. They are currently trialing an ensemble prediction system based on this model configuration.

Figure 2 Example of a wind speed and direction prediction at full resolution for part of the south coast of England from the operational 1.5 km grid model of the UK Met Office showing detailed wind responses to the headlands of Portland and Swanage and through the channel between the Isle of Wight and Southampton. (Wind speeds are in knots.)

Figure 3 Some European domains implemented by operational users of the COSMO model showing a variety of compromises between covering a large area and focusing high resolution on a single country.

The United States National Centre for Environmental Prediction runs a regional model for the whole of the North American continent and a higher resolution model for the contiguous states. Current operational models have a grid length of 12 km, but trials are at an advanced stage to move to a 3 km grid configuration.

The HIRLAM (high resolution limited area model) has been developed by a consortium of Nordic and other European countries. It is a grid point, hydrostatic model. The participating countries use it in a variety of configurations according to their operational requirements.

Convective Storm Modeling

MD Parker, North Carolina State University, Raleigh, NC, USA

© 2015 Elsevier Ltd. All rights reserved.

Synopsis

Numerical models have been central to a wide range of advances in the knowledge of convective storm dynamics. Many long-standing research findings emerged from carefully controlled sensitivity experiments in early, highly idealized model configurations. Over time, convective storm simulations have become increasingly realistic, thanks to decreases in grid spacing (permitting resolution of subcloud turbulent eddies), more sophisticated treatments of precipitation microphysics, and increased understanding of how often-neglected processes (e.g., radiative fluxes) may influence the conclusions from traditional idealized models.

Introduction

The use of numerical models is extremely popular in the convective storms research community for a number of reasons. Firstly, the governing equations for convection do not have analytic solutions except in very specialized cases. And, secondly, the small-scale details of convective storms are rather hard to observe. High-resolution remote sensing and surface measurements are indeed available from a handful of field experiments. However, the primary wind and thermodynamic variables are usually measured too sparsely to support computation of temporal and spatial derivatives needed for studies of storm dynamics, and *in situ* thermodynamic observations are almost nonexistent aloft. In contrast, numerical model output is dense and conveniently gridded, making it possible to directly compute physically meaningful tendencies and budgets at very high resolution.

Models are also internally consistent dynamical laboratories, providing an extremely effective means for controlled hypothesis testing; inputs can be varied across model experiments (something not possible with observed real-world cases). Idealized models also provide the possibility for reducing the complexity of meteorological problems, in the interest of isolating and understanding important processes. Historically, theory and modeling of convective storms have advanced hand in hand. New theories can readily be tested in models (whereas they are often challenging to validate with conventional observations); in turn, theory is often advanced by attempting to explain sensitivities and behaviors produced by models.

Operational numerical weather prediction (NWP) with models has also recently realized the capability to forecast convective storms explicitly, albeit coarsely (such models are commonly referred to as ‘convection permitting’). This approach has produced some notable successes in predicting timing of convective initiation and the subsequent predominant convective mode. The numerical underpinnings of NWP forecasts are fundamentally the same as those for process study simulations, although the resolution of NWP model runs is usually coarser (due to operational time demands). Whereas real-time convection-permitting forecasts are of great operational importance, the majority of the model-driven advances in our understanding of storm behavior have emerged from more idealized simulations configured for research.

Typical Experimental Design

All of the models currently used for convective storms research could be considered cloud models. In principle, one can use any model that is nonhydrostatic (since vertical accelerations are generally large in convective storms) and represents moist processes, provided it has subgrid-scale and physical parameterizations appropriate for the grid spacings at which convective storms are typically simulated. Most modern cloud models are fully compressible and use techniques such as timestep splitting in order to retain stability while simulating the effects of acoustic waves. Almost all such models use an Eulerian staggered grid (the Arakawa C grid), and perform finite differences using the grid volume-averaged equations. The coordinates may be either Cartesian or terrain-following, and the vertical coordinate may be either height based or mass (pressure) based. Because very high resolution is generally demanded for convective storm simulations, techniques such as grid stretching (primarily in the vertical) and grid nesting (primarily in the horizontal) are often used in order to construct large domains in a way that is computationally affordable.

Starting with the original convective storm simulations that emerged in the 1970s (many using the Klemp–Wilhelmson model, perhaps the first well-established code for the specific purpose of convective storm modeling), typical experiments have employed highly idealized configurations, including horizontally homogeneous initial conditions. In such cases, the simulated convective evolution is understood to be a fundamental response to a representative environmental sounding. Two rather popular initial conditions for convective storm simulations are the sounding from the 20 May 1977 Del City, Oklahoma tornado, and the idealized analytic sounding created by M. Weisman and J. Klemp (known colloquially as the ‘Weisman–Klemp’ sounding) (Figure 1). These soundings are useful benchmarks for sensitivity tests because they are easy to incorporate and are known to produce robust storms in a variety of numerical models. As a part of such sensitivity tests, simplified wind profiles have also been frequently used, including straight-line, quarter-turn, and half-turn hodographs of varying lengths (Figure 1).

Homogeneous model environments are convenient for this kind of experimentation because they allow the user to independently vary the initial thermodynamic and wind profiles without needing to adjust background horizontal gradients

Figure 1 Skew- T log- p diagram and hodograph plot for several traditional soundings and wind profiles commonly used in idealized convective storms models. The temperature, humidity, and vertical wind profiles for the 20 May 1977 Del City, Oklahoma, tornado are plotted in green. The temperature and humidity profiles of the idealized Weisman–Klemp sounding are plotted in red. Several additional idealized wind profiles (often used in tandem with the Weisman–Klemp sounding) are plotted on the hodograph, including a simple straight-line profile (light blue), a quarter-turn supercell-like profile (dark blue), and a half-circle supercell-like profile (purple). The altitudes of the surface, 1, 3, and 6 km data points, are annotated with symbols on the hodograph curves as shown.

(i.e., to maintain large-scale thermal wind balance). Open (or ‘radiative’) lateral boundary conditions can be easily used, and even more simplified mirror or periodic conditions are possible, where the geometry of the problem supports it (an example using a periodic boundary condition is shown in [Figure 2\(b\)](#)). When combined with a free-slip model bottom, such boundary conditions allow the homogeneous environment to remain steady in time, and simple simulation results to become very nearly Galilean-invariant.

These traditional idealized model experiments have typically included few (or no) parameterizations of processes other than subgrid-scale turbulence and precipitation microphysics. Although it is now known that surface fluxes, planetary rotation, and radiation are potentially important to convective evolution, such processes were long neglected in convective storm models for reasons of computational affordability. Even today, highly idealized approaches remain popular because simpler simulations allow for controlled hypothesis testing using a small number of well-known inputs. Indeed, because of the highly nonlinear interactions in full-physics storm simulations, a wide range of even more idealized simulations (which might generally be called ‘toy model experiments’) has also been devised. Such simulations might not even include an actual convective storm (perhaps only a stormlike heat source or sink).

Using whatever degree of simplification, a single idealized model run is not especially useful by itself because its volatility is unknown. Since many details are omitted from the model configuration, exact correspondence to an observed case is unlikely. Additionally, artificial forcing is often needed in order

to produce convective development, particularly in horizontally homogeneous environments (which lack preexisting fronts and mesoscale circulations). Common artificial triggers include idealized warm thermals, cold pools, convergence zones, and surface fluxes. Typically, after storms have developed in response to the artificial trigger, research then focuses on how the storms freely evolve within the environment. However, owing to the somewhat improvisational initial forcing, only a basic credibility check of the results is often possible. Therefore, trends among multiple runs tend to be more meaningful than the specific output values from any one run. The true strengths of the idealized approach lie in robust sensitivity testing and determination of basic cause–effect relationships.

A great deal has been learned from such simulations, and they continue to have pedagogical value. However, advances in understanding and in computer power have increasingly driven the field toward more sophisticated approaches. Hybrid idealized approaches have emerged in which some horizontal or temporal variability is permitted within the context of an environment that is still closely controlled. Also, a complementary body of work has emerged using case study simulations. In such simulations, direct observations (or analyses from larger scale models) are used for the model’s initial and boundary conditions. As a result, the forcing for storms is a natural property of the large-scale environment (no artificial triggering is needed), and the expectation is that model output that will correspond to specific observations from the chosen case. In order to accomplish such realism, a model must include many more components (e.g., representations

Figure 2 Plan views of radar reflectivity (shaded, dBZ) for (a) an observed squall line (Wilmington, Ohio, radar from 2113 UTC on 29 June 2012), (b) an idealized simulated squall line (using the traditional Weisman–Klemp sounding and a straight-line wind profile as shown in Figure 1), (c) an observed supercell (Amarillo, Texas, radar from 2327 UTC on 18 May 2010), and (d) an idealized simulated supercell (using the traditional Del City, Oklahoma, tornado sounding and wind profile shown in Figure 1). The size of the domain for panel (b) is shown by the dashed rectangle in panel (a). The horizontal scales are identical in panels (c) and (d). Characteristic features of squall lines and supercells are annotated. Because there are no clear-air radar targets to produce a ‘fine line’ in the squall line simulation, in panel (b) the gust front is instead indicated by a black contour of potential temperature perturbation (θ') = -2 K. All of the simulations were performed using a 250-m grid spacing. The simulated squall line in panel (b) is an example of using a periodic lateral boundary condition in the y -direction to minimize the computational expense of the domain.

of terrain, land cover, radiation, and boundary layer flux profiles).

Because numerical models (and the atmospheric equations themselves) have a sensitive dependence on initial conditions, and because there is often very little information for initial conditions on the scales of convective storms themselves, in practice it is still very difficult to replicate an observed case. Even so, such models can still be useful as internally consistent proxies for the kinds of storms that develop in a particular regime. Additionally, with advances in data assimilation techniques that have the capability to ingest Doppler radar observations, it is becoming possible to constrain case study simulations and produce results that match the placement and structure of observed storms more closely. Ensembles of simulations have also increasingly been used to quantify probabilities and uncertainties present in case study modeling results, providing a more statistical view of convective behavior. The configurations of case study simulations are also generally more appropriate for direct assessment of the

strengths and weaknesses of operational convection-resolving NWP models.

Explicit Representation vs Parameterization of Important Processes

If an important process is too small in scale to be adequately represented by a model’s grid spacing, then a ‘parameterization’ is developed (based upon theory and/or observations) that allows the model fields to respond as though the missing process was present. Models used for convective storms research are always convection permitting (i.e., the storms are not parameterized). However, the fact that the convection is permitted (occurring on the model grid) is not necessarily the same as saying that the convection is well resolved (properly represented). As in all model simulations, great caution is needed to avoid attaching significance to simulated features that are poorly resolved.

Because there is generally not sufficient computer power to run convective storm simulations at grid spacings where the solutions are ‘converged’ (that is, no longer sensitive to further decreases in grid spacing), grid spacings are generally chosen based upon the scales of the processes thought to predominate the problem of interest. Extensive testing has shown that gross mesoscale structures of convective systems begin to be resolved with horizontal grid spacings of 1–4 km (Figure 3). Because the vertical gradients of most variables tend to be comparatively large, such simulations still typically use vertical grid spacings that are <1 km. However, current conventional wisdom is that a proper representation of convective storms requires explicit treatment of the largest eddies that account for entrainment and mixing within clouds and at cloud edges. Such eddies first emerge in simulations as grid spacings decrease from roughly 500 toward 100 m (Figure 3). Sensitivity tests have shown that simulations with grid spacings >500 m have too little turbulent kinetic energy on the scales of importance to convective clouds (Figures 3 and 4).

Even within highly idealized convective storm simulations using small grid spacings, the treatments of turbulence and precipitation microphysics are of great importance. A number

of frequently neglected processes such as surface fluxes and radiation also require parameterization if they are to be included in convective storm models.

Treatment of Turbulence

Turbulent mixing is a fundamental part of convective motions in the atmosphere, and yet this important process is only marginally resolved in most modern convective storm simulations. It is still rather rare for full convective storm simulations to have grid spacings that would be consistent with large eddy simulations (LES, commonly having grid spacings below 100 m), mainly due to computational expense. When grid spacings on the order of tens of meters have been used, it has typically been in the context of shallower clouds (boundary layer cumuli and congestus, stratocumuli), or for detailed simulations of tornadoes (without their parent thunderstorms).

Even in true LES models, a subgrid-scale parameterization is needed to represent the effects of turbulent motions smaller than what the model can explicitly predict. The typical treatment assumes that the smallest resolved scales fall within the

Figure 3 Contemporaneous vertical cross sections of vertical velocity (shaded) and cloud outline (black contours) for a developing convective storm in simulations with varying grid spacings (as labeled in each panel). Each simulation uses the traditional Weisman–Klemp sounding shown in Figure 1, a resting base state, and an identical warm thermal trigger with additional random noise inserted into the initial potential temperature field.

Figure 4 Contemporaneous along-line vertical velocity spectra (kinetic energy per unit mass) at 5 km above ground for a suite of idealized squall line simulations using different grid spacings (keyed to the line styles as shown). A thick gray line corresponding to a $\kappa^{-5/3}$ spectrum is included to illustrate behavior that is expected in an inertial subrange. Reproduced with permission from Bryan, G.H., Wyngaard, J.C., Fritsch, J.M., 2003. Resolution requirements for the simulation of deep moist convection. *Monthly Weather Review* 131, 2394–2416.

inertial subrange, such that basic ‘K-theory’ for eddy viscosity (or diffusivity) can be applied to represent the mean downscale energy transfer within the unresolved scales. This kind of parameterization is used in almost all convective storm models. However, it appears that the characteristic $\kappa^{-5/3}$ slope of an inertial subrange (at scales beneath the energy peak on a log–log spectrum plot, where κ is the wave number) may not be well depicted in storm simulations with grid spacings ≥ 500 m (Figure 4, where the gray line has a slope of $-5/3$ for reference).

The downward slopes steeper than $\kappa^{-5/3}$ to the far right in Figure 4 are due to excessive energy losses from numerical filtering, which limits the effective resolution of the model; on coarser grids, this limitation prevents faithful depiction of even the largest eddies within the inertial subrange, and the $\kappa^{-5/3}$ regime vanishes. Based on such analyses, grid spacings of roughly 250 m (or less) seem to be the minimal requirement for appropriate convective storm modeling with LES-like sub-grid-scale parameterizations. Computer power has now increased to the point that such runs are practical for most experiments. However, smaller scale convective features (e.g., tornadoes) require still finer grid spacings than this.

Treatment of Cloud and Precipitation Microphysics

The treatment of cloud and precipitation microphysics is entirely parameterized in all modern models, and is one of the most important components of convective storm simulations. Microphysics is extremely influential on the dynamics, contributing to heating in regions of condensation, riming, and freezing, to cooling in regions of evaporation, melting, and

sublimation, and to downward accelerations from hydrometeor loading. The proper representation of hydrometeors is also important for the correct treatment of radiation (i.e., shading and absorption of upwelling longwave radiation) in models that include such processes.

Microphysical parameterization also may be the largest source of uncertainty in modern convective storms models. Recent studies have shown large sensitivities to seemingly minor features such as details of the hail category (whose subsequent fall speeds partly determine the horizontal footprint of convective precipitation) and treatment of raindrop breakup (since drop sizes have a major influence on fall speeds and evaporation rates). Unfortunately, many such components are rather poorly constrained by measurements. Therefore, substantial uncertainties exist even in the most modern microphysical parameterizations.

First-generation microphysical treatments (a popular example in convective storms modeling is the well-known ‘Kessler scheme’) included only bulk treatments of water vapor, cloud droplets (which are assumed to move with the flow and have a negligible fall speed), and raindrops (which are assumed to have a nonzero fall speed). Most such schemes assume that cloud droplets are monodisperse and that raindrops have the commonly observed inverse-exponential (Marshall–Palmer) size distribution. The slope of the drop size distribution is generally related to the predicted rainwater mixing ratio with the idea that, as mixing ratio increases, the number of small drops is relatively unchanged while the number of large drops increases the most (proportionally). Such schemes usually assume that cloud water is produced instantaneously when supersaturation exists, whereas rain is

produced over time from cloud water (e.g., via collision and coalescence). Physical relationships and empirical formulations are then used to represent the rates of important processes such as conversion of cloud to rain, evaporation, and fallout.

Such liquid-only parameterizations produced storms that were recognizable, and enabled early studies to diagnose fundamentals such as the mode of convective organization. However, some of the simulated features were unrealistic, especially because of the exclusion of ice. The subsequent addition of bulk treatments for cloud ice and snow (in a similar fashion to cloud water and rain) was shown to improve the realism of convective storm anvils as well as zones of moderate (stratiform) precipitation within mesoscale convective systems (MCSs). These improvements are largely attributable to the much smaller fall speeds of snow (compared to rain), but also because the inclusion of freezing and melting adds realism to the vertical structures of updrafts and downdrafts. Recently, some advanced schemes have further differentiated between unique subcategories of snow (columns, plates, dendrites, aggregates, etc.), presumably because the growth and fallout properties of ice are sensitive to the predominant ice crystal habit.

At the very least, most modern bulk parameterizations also include a rimed ice category for added realism. This category is ordinarily tuned to represent either hail or graupel, with the primary difference being the assumed density of the particles (traditionally, 900 kg m^{-3} for hail vs 400 kg m^{-3} for graupel). This choice in turn influences the computed fall speeds of the rimed ice. For many historical convective storm simulations, hail has been preferred. Hail particle trajectories are more clearly distinct from snow, providing more realistic horizontal distributions of light vs heavy precipitation in supercells and squall lines. The choice of hail also generally leads to more realistic (weaker) surface cold pools due to the larger fall speeds and smaller surface area per unit volume (in comparison to graupel). Of course, in nature there is a spectrum of densities for rimed ice particles and, in stratiform regions of MCSs for example, the less dense graupel category may be more realistic. Some recently developed parameterizations now either predict both categories of rimed ice, or else allow for variable graupel/hail density as a predicted function in the model (based upon the assumed hail growth regime).

Contemporary studies have also suggested that different regions within storms are better described by different ‘intercepts’ of the inverse-exponential size distribution. Such results imply that it may not be possible to configure a single-moment scheme (which predicts only the hydrometeor mixing ratios) to properly handle the entire system. Therefore, a present trend in convective storms modeling is toward multimoment microphysical parameterizations. Double-moment schemes predict total number concentrations (in addition to mixing ratios), which allows for diagnosis of the ‘intercept’ of the inverse-exponential size distribution. Therefore, the concentrations of large and small drops can evolve somewhat independently from one another. This provides a better representation of processes such as size sorting and the preferential evaporation of smaller drops. Recently introduced triple-moment parameterizations allow even more extravagant descriptions of the size distribution (i.e., deviations from the simple inverse-exponential relation). Tests have shown that some

multimoment schemes produce more realistic convective cold pools and reflectivity structures than single-moment schemes (Figure 5). However, these higher order schemes also have many more free parameters. It is not always clear whether such settings are well constrained by observations or theory, and yet they have been shown to produce very large model sensitivities.

Some modern models are also now beginning to predict the concentrations of condensation aerosols interactively, using them as input to the precipitation scheme. Aerosols may influence the hydrometeor size distributions, both in terms of initial droplet concentrations and in terms of the rates and locations of subsequent growth by coalescence and riming. In turn, as the sizes and spatial arrangements of hydrometeors change, the footprint of potential cooling in the storm also may change. These effects have been shown to be nonzero, although there is still debate about their relative importance in comparison to the basic environmental ingredients that strongly control storm dynamics.

Apart from the above bulk microphysical schemes, there are also a number of models using ‘bin-resolving’ treatments that represent the hydrometeor size distributions through the use of discrete ‘bins.’ These bins are defined based on ranges of mass or size (with mass doubling being a typical approach for determining the thresholds). Because no a priori shape is assumed for the particle size distributions, they are free to evolve independently, with the mass and/or number concentrations of hydrometeors in each bin being continually predicted. Up until recently, the number of calculations required for each individual bin was considered too computationally expensive, and the approach was thus rare. However, with advances in computer power, it has become more practical (although still requiring limits in domain size). Some researchers have also used ‘bin-emulating’ schemes, which achieve much of the accuracy of bin schemes (while maintaining the computational efficiency of a bulk scheme) by only temporarily partitioning a bulk size distribution into bins and then deriving microphysical tendencies from predetermined lookup tables.

Treatment of Other Subgrid-Scale Processes

The inclusion of surface fluxes, realistic boundary layers, and radiative forcing is increasingly viewed as both practical and desirable for convective storm simulations. Historically, such features have often been ignored both for computational efficiency and to simplify interpretation of the primary dynamics involved in convection–environment interactions. For example, in runs with surface fluxes of momentum (i.e., surface drag), the traditional use of a homogeneous base state becomes complicated because there is no large-scale pressure gradient to oppose deceleration of the flow by surface drag. Naturally, real storms do occur in environments where surface fluxes of buoyancy and momentum drive an actively mixed boundary layer; also, real storms experience feedbacks from shortwave shading produced by their cloudiness, as well as net longwave cooling at their cloud top levels. The addition of parameterizations for these processes has begun to provide a clearer understanding of their roles in storm dynamics.

It appears likely that surface fluxes (particularly of momentum) are necessary to properly represent the

Figure 5 Contemporaneous plan views of surface equivalent potential temperature perturbation (shaded), reflectivity (contoured with a 10-dBZ increment), and horizontal ground-relative wind vectors (plotted every 2.5 km, 1 step = 15 m s^{-1}) for simulations using a 500-m grid spacing and the following microphysical parameterizations (all of which include ice): (a) the Lin–Farley–Orville single-moment scheme, (b) the Lin–Farley–Orville single-moment scheme with a reduced rain intercept (producing larger drops on average), (c) the Milbrandt–Yau single-moment scheme, (d) the Milbrandt–Yau double-moment scheme, (e) the Milbrandt–Yau double-moment scheme with a diagnostic relationship for the shape of the size distributions (simplistically emulating a triple-moment scheme), and (f) the full triple-moment Milbrandt–Yau scheme. Adapted with permission from Dawson, D.T., Xue, M., Milbrandt, J.A., Yau, M.K., 2010. Comparison of evaporation and cold pool development between single-moment and multimoment bulk microphysics schemes in idealized simulations of tornadic thunderstorms. *Monthly Weather Review* 138, 1152–1171.

tornadogenesis process as it occurs in nature. Indeed, some recent studies have found surface friction to be a leading term in the calculated vorticity budget. Realistic variations in soil moisture within such runs may also dramatically modulate the environmental boundary layer relative humidity (and thus convective available potential energy (CAPE) and evaporative potential). Other recent results also suggest that, although the net effect of boundary layer circulations may be modest, storms become increasingly unsteady as they interact with boundary layer rolls and eddies in simulations with heterogeneous surface fluxes. Finally, it appears that stabilization from convective anvil shading can have a noticeable influence on both low-level stability and the low-level vertical wind profile (due to changes in vertical mixing). Such lower tropospheric changes can directly impact the storm dynamics.

When the aforementioned processes are included, some of the traditional tenets of convective storm modeling have to be reexamined. For example, in classical simulations with free-slip bottom boundaries (i.e., no surface fluxes), the dynamics are presumed to be Galilean invariant: this enables scientists to run simulations in which the storm remains conveniently stationary within the model grid. However, surface fluxes are sensitive to the ground-relative wind, and summed radiative tendencies are influenced by the grid-relative motion of cloud.

So, larger domains are generally needed in order to use native wind profiles in simulations with these processes included.

Further parameterizations of processes like electrification and lightning are also sometimes used, although these tend to be passive end products of the dynamical and microphysical fields, and do not feed back upon them (with the exception that lightning parameterizations are sometimes coupled to chemistry models, a topic not addressed in detail here).

Historical Applications and Results

Convective storm models have a history of success in replicating most observed features of storms. In turn, analysis of output from such models has helped to spell out the ways in which convective evolution is linked to the environmental profiles of winds, temperature, and humidity. Because of their great societal impact, squall lines (including MCSs) and supercells have received the most attention (Figure 2), with much investigation of their dynamics and environmental sensitivities.

The earliest models of convective storms were for ‘proof of concept,’ and mostly used either axisymmetric or 2D (slab) symmetric geometry with only crude microphysics. From such

models, basic explanations for processes such as downdraft forcing and density current evolution began to emerge. Subsequent 2D and 3D runs (beginning in the late 1970s) established the important role of vertical wind shear in determining storm type. It became clear that, in undisturbed environments, disorganized ordinary cells would occur in weak vertical wind shear, with multicells in moderate shear (e.g., [Figure 2\(a\)–2\(b\)](#)) and supercells in strong shear (e.g., [Figure 2\(c\)–2\(d\)](#)). Sensitivity tests showed that the transitions between these storm types can be surprisingly abrupt. Likewise, early simulations began to establish the important role of CAPE (a metric that was not nearly so widely used prior to the convective storm modeling era) upon storm structure, intensity, and outflow production. Subsequent climatologies have largely validated the parameter sensitivities suggested by models, and in turn the models have helped to explain the physical reasons why the sensitivities exist.

Squall Lines and Mesoscale Convective Systems

Although almost every modern simulation is now carried out in 3D, squall lines were one of the first storm types to be studied extensively because their natural structures (with much larger across-line gradients than along-line gradients, e.g., [Figure 2\(a\)](#)) could be reasonably represented in affordable 2D slab-symmetric models (or smaller periodic 3D ‘channel’ models, as in [Figure 2\(b\)](#)). Early modeling results helped to articulate the role of interactions between the system outflow and the lower tropospheric line-perpendicular environmental vertical wind shear. A combination of simulations and theory explained the tendency for squall lines to exhibit continued redevelopment of convection on the down-shear edges of their outflows, the propensity for squall lines to produce severe winds and heavy precipitation in strongly sheared environments, and the common observation that squall lines tend to evolve toward a structure with trailing stratiform precipitation as their cold pools intensify.

Once such fundamentals were established, subsequent modeling work helped to articulate how important features such as rear inflow jets, midlevel mesoscale convective vortices, and near-surface line-end vortices form. Many of these phenomena had already been capably studied using observations, but model simulations provided the first truly controlled experiments that isolated the most important processes. In tandem, some extremely simple (toy model) simulations revealed that the vast majority of mesoscale circulations within and around squall lines and MCSs can be regarded as simple responses to the footprint of latent heating in the system. In understanding the dynamics of these mesoscale features, a comprehensive conceptual model emerged for the genesis of bow echoes and severe surface winds as well. The important roles of both line-parallel vertical wind shear and upper tropospheric vertical wind shear also became increasingly apparent from simulations, and such findings enabled a more realistic representation of a wider range of observed MCS structures and behaviors.

The era of widespread 2D squall line simulations came to a close shortly after the turn of the century, as the dynamics of the constituent convective cells were repeatedly shown to be decidedly 3D. Models revealed that many squall lines possess

low-level slablike lifting, but discrete cellular updrafts farther aloft, with the height and abruptness of this transition being very strongly linked to the cold pool strength. The regular pulsing of the individual updrafts in squall lines was further linked to a self-driven mechanism that cuts the cells off the gust front, and modeling studies also revealed that gust front lifting can produce moist absolutely unstable layers, which in turn break down into embedded 3D roll-like circulations. Although such results have not generally invalidated the original conclusions from most of the pioneering 2D modeling studies, they provide a much clearer explanation for many of the small-scale features that are regularly observed (e.g., with radar) in real-world squall lines and MCSs.

Recently modeling work has also advanced the knowledge of several operationally important subsets of squall lines. Nocturnal and elevated (that is, having inflow well removed from the surface) MCSs are common in nature, and simulations have provided a clearer understanding of the mechanisms responsible for sustaining squall lines during the overnight hours and in environments where a surface cold pool does not develop (or is quite weak). Such studies have highlighted the important roles of gravity waves and bores in MCS maintenance, and the intricate interplay between stability and vertical wind shear in such cases. Finally, model simulations have largely driven the discussion of possible mechanisms for the formation of intense surface mesovortices within the gust fronts of mature squall lines, which remain poorly understood and present significant hazards to society.

Supercells and Tornadoes

Once 3D simulations became practical, a great many idealized simulations focused on understanding the basic dynamics and environmental sensitivities of supercells. Much of the earliest evidence for supercellular storm splitting came from simulations (and the behavior was subsequently observed to be quite common, e.g., [Figure 2\(c\) and 2\(d\)](#)). Confounding some intuitive speculations, models further showed that storm splitting was primarily a dynamically driven process, and did not require the presence of a precipitation-driven downdraft. Many far-reaching impacts of dynamic pressure effects upon supercell motion, intensity, and longevity were largely demonstrated with models, including the understanding that right-moving supercells are favored over left-moving supercells in most midlatitude Northern Hemisphere environments because the vertical wind shear vector turns clockwise with height.

Appreciation of these modeled dynamical influences also led to the maturation of diagnostic pressure analysis in convective storms research, and the related partitioning of accelerations into buoyant and dynamic components. Such approaches demonstrated, for example, that the sounding-based approach of inferring vertical motion from CAPE was likely to substantially underestimate the strength of supercell updrafts, which profit from additional upward accelerations due to dynamical contributions.

Prior to the era of 3D storm modeling, the origins of vertical vorticity and its subsequent evolution in supercells had long been the subject of interest. Gridded model output fields permitted computation of reasonably accurate trajectories and

budgets, demonstrating the source regions for air parcels in different parts of the storm, and enabling the assessment of circulation around material circuits that are advected by the model winds. Such techniques confirmed that the primary source of midlevel updraft rotation was the horizontal vorticity of the sheared background environment, whereas the source for supercells' low-level mesocyclones was revealed to be baroclinic generation of horizontal vorticity in the forward flank. This knowledge led to a new generation of tornadogenesis hypotheses invoking baroclinity and emphasizing the importance of the storm downdrafts and outflow.

It also had been long surmised that supercells interacting with preexisting outflow boundaries or fronts might intensify (and become more likely to produce a tornado). The beneficial contribution of enhanced low-level shear on the cool sides of such boundaries (as compared to the hindering effect of increased stability) was cleanly isolated in controlled model experiments that studied the same storm both with and without a boundary crossing.

Many such modeling studies have assessed tendencies in the low-level rotation of supercells, and have speculated about the possible ramifications to tornado formation. However, proper representation of a tornado likely requires model grid spacings on the order of 10 m. Therefore, most historical tornado simulations focused only on the vortex itself within a small domain, omitting the parent supercell for computational economy. Such studies have revealed a great deal about tornado structure and dynamics, but the real-world context for tornado formation was missing. Amazingly, some of the most central tenets of modern tornado theory emerged from very simple (toy model) simulations that demonstrated the need for a downdraft in order to produce a surface vortex in environments without preexisting vertical vorticity.

Early attempts to model full supercells with tornado-like vortices normally involved grid nesting near the tornado; unfortunately, it was never clear how the abrupt change in model resolution influenced the production and strength of the simulated vortex. The computers of today (and the future) make it possible to use high resolution over a much greater fraction of the model domain and for a much longer period of simulation. As an increasing number of studies attempt this approach, proper treatments of surface drag and small-scale turbulence are emerging as critical components of the experiments.

Future Directions

A great deal has been learned from convective storms modeling since the 1970s, and yet some very basic processes remain mysterious. For example, the genesis mechanisms of tornadoes and gust front mesovortices are still not well understood, and it is not yet clear how storms develop and maintain themselves in a variety of inhospitable environments. Given ongoing difficulties in making the small-scale measurements needed to address such questions, models will likely remain a cornerstone of convective storms research.

As computer power advances, the trends toward decreasing grid spacing and more sophisticated scale-appropriate parameterizations will no doubt continue. In addition, greater numbers of simulations will be possible for an individual experiment or

forecast. This will enable scientists to explore a much broader parameter space (in terms of convective ingredients), and also to exploit ensemble techniques (which specifically quantify the uncertainties in experiments and forecasts).

Larger ensembles also add value to modern data assimilation techniques (e.g., the ensemble Kalman filter). For example, assimilation of radar data into both case study and idealized model simulations has already become practical. Radar data may be assimilated at intervals of a minute or less, and preliminary results suggest very good agreement between observed and simulated storms. Such techniques will provide additional observational constraints upon research simulations, and will open up the possibility of deterministic or probabilistic short-term severe weather forecasting using convection-permitting models.

Regional forecast models already marginally resolve convection, and regional climate models will soon. This will likely open up new linkages to the forecasting of hydrology and severe weather, and to prediction of changes in convective weather under future climate scenarios. Meanwhile, idealized research simulations will continue to incorporate more realistic features, including long-neglected processes such as radiation, boundary layer circulations, and storm interactions with environmental heterogeneity and terrain. It will be of interest to learn how such complexity influences our view of convection, which currently is largely based on sensitivities to environmental ingredients within highly simplified model configurations.

Synopsis

Balloons are unique tools for studying the atmosphere. In contrast to satellites providing a global view of the Earth's atmosphere at broad resolution, they allow investigating atmospheric processes at high resolution. Following the meteorological balloon-sondes at the end of the nineteenth century, powerful vehicles have been designed using plastic films available since 1947. Since then a number of balloon platforms have been designed spanning from zero pressure balloons flying up to 40 km altitude, spherical or pumpkin super-pressure balloons and Infrared Montgolfier allowing long duration flights for several months, and tethered balloons for studying the lower atmosphere.

Introduction

Though a large number of high-performance satellite instruments have been placed into orbit during the last decades, balloons are used more frequently than ever in studying the atmosphere, for several reasons. Indeed, if satellites are unique in providing a global view of the Earth's atmosphere, they also suffer several limitations. First, because of atmospheric attenuation and clouds, chemical species as well as meteorological parameters can only be observed from satellites with difficulty at altitudes below 20 km, i.e., in the lowermost stratosphere where ozone depletion takes place, and in the troposphere where the impact of human activities could be the largest. Moreover, the vertical resolution of the measurements from satellite is limited to 1–2 km at best, and several important chemical species could not be derived by remote sensing techniques. Finally, satellites have a limited lifetime. Except for ozone, at present they do not allow the long-term monitoring of the composition of the atmosphere, a vital necessity in understanding the impact of anthropogenic sources and the relation between chemistry and climate.

In contrast, currently available balloons allow a variety of *in situ* and remote sensors, making measurements from the

ground to about 40 km, to be carried at relatively low cost, thus allowing the repetition of the measurements over a long period. Importantly also, balloon flights can be performed within a shorter time frame than that required for the development of space projects, allowing the rapid checking of new ideas, concepts, or instruments for further use in space and later the validation of the measurements of spaceborne instruments.

Furthermore, long-duration balloon systems of various types are currently available or under development, which should allow greater use of balloons in atmospheric studies on a global scale at a relatively low cost.

Just as meteorological satellites did not replace the need for several hundred daily radiosonde ascents, so space instruments did not replace the use of balloons, but in contrast resulted in their considerable development. This, together with the use of modern space technology in the instruments and payloads design, i.e., Iridium satellite transmission, Global Positioning System (GPS), explains why scientific ballooning has been taken up by space agencies in most countries.

The objective of this article is to give an overview of the unmanned balloon systems currently available or under development for atmospheric research. After a brief historical recall of scientific ballooning and of those conceptual aspects needed to understand how balloons work and their

limitations, the main systems currently available will be described from the point of view of the scientific user.

History

Balloons are not new vehicles. They all still rely on one of the two concepts both flown for the first time in 1783 in France: hot air by the Montgolfier brothers and gas by Charles and Robert. As a first step for about a century, these balloons were used primarily for spectacular events during celebrations, were all manned, and were used little for science. The first observations of scientific interest were those of Robertson in 1803 and of Gay-Lussac and Biot in 1804. They demonstrated the decrease of temperature, pressure, and moisture with height and the constant composition of air up to an altitude of 7000 m. But progress was slow, limited by the maximum altitude acceptable to the pilots. Only a handful of ascents of scientific interest were performed during the nineteenth century. Barral and Bixio in 1850 in France discovered the existence of ice particles – cirrus clouds – forming at low temperatures at 7000 m. In 1852, Welsh and in 1862, Glaisher in the United Kingdom extended observations to a record altitude of 8800 m. Then, Sivel, Croce-Spinelli, and Tissandier in France in 1875 made the first spectroscopic observations of astronomical bodies above the dense atmosphere at 8600 m, during an ascent in which the first two men perished. Finally, Berson in Germany, reaching 9150 m in 1894 and 10 300 m in 1901, measured a record low temperature of -47.91°C .

Though manned flights were continued into the next century (Piccard in 1931 reached 15 781 m, followed shortly after by Prokofiev, Goudonov, and Brinbam in the Soviet Union at 18 500 m, Settle in the United States at 18 665 m, and several others until Kittinger reached 30 000 m in the United States in the 1960s), the greatest progress in atmospheric science and meteorology was to come from the use of unmanned balloons.

The first series of unmanned ascents for studying the upper atmosphere was performed by Hermite and Besançon in 1892 in France; they used an onboard recording thermometer, barometer, and hygrometer designed by the meteorological instrument manufacturer Richard. These were recovered after the flight. This was followed by the installation of the first upper air sounding station at Trappes near Versailles by the meteorologist Teisserenc de Bort. Thanks to this effort, the stratosphere was discovered in 1898. The stratosphere was shown to be a region, where the temperature did not continuously decrease to the absolute zero around 50 km as thought before, but instead leveled off or even increased above 12–13 km. The next important technical step forward was that of Assmann in Germany, who in 1901 suggested the use of small rubber dilatable balloons and a parachute for safe recovery of the instruments. With such a system, a record altitude of 37 700 m was reached at Pavia in Italy in 1912. The further significant step is due to Hergesell, who in Germany in 1910 performed the first wind sounding using a theodolite on the ground to follow the horizontal motion of the balloon during ascent, while the altitude of the balloon was reckoned using a simple stopwatch. But the major breakthrough in atmospheric science was the invention of the radiosonde by Idراع and Bureau in

1929, who added a radio transmitter to send the temperature, pressure, humidity, and wind information in real time, thus eliminating the need to wait for an unpredictable and sometimes very long recovery of the sonde. Though many improvements have been added since (e.g., neoprene balloon material, much more sensitive sensors, miniaturized electronics, Omega, and later the GPS for the location of the sonde), the radiosondes in use today in the upper-air network of the World Meteorological Organization are basically the same as in 1929.

However, because of the restricted load permitted below rubber balloons, or the weight and therefore the altitude limitation of manned systems, the use of balloons for science other than meteorology remained limited until the arrival of plastic film in 1947 developed by Winzen at General Mills in the United States. Astronomers or cosmic ray scientists as well as atmospheric scientists were immediately interested in the new technique to carry heavy payloads above the absorbing atmosphere. Modern scientific ballooning had started by the late 1950s in the United States under the direction of Ney at the University of Minneapolis, later transferring to the National Center for Atmospheric Research (NCAR), and then to the National Aeronautic and Space Administration (NASA). Soon after, scientific ballooning activities were also started in France by Blamont at the Centre National de la Recherche Scientifique, later transferring to the Centre National d'Etudes Spatiales (CNES). Thenceforth, the technology propagated rapidly in the 1960s in the Soviet Union, Japan, India, Indonesia, Brazil, and Argentina, though complete balloon manufacturing capabilities were not available in most of the latter countries.

A variety of balloons were progressively made available to atmospheric scientists, and ranged from open or zero-pressure balloons carrying heavy payloads for a few hours at high altitude to long duration for a few weeks or months in the lower atmosphere. Though their performances and uses varied, they all followed the same physical principles, which are recalled below before describing current available platforms.

Balloon Concepts

The lift of a balloon, derived from Archimedes' principle, can be expressed as

$$V(\rho_{\text{air}} - \rho_{\text{gas}}) = \Sigma M_s(1 + f)$$

where V is the volume, ρ_{air} and ρ_{gas} are the densities of air and the lifting gas (hydrogen, helium, or hot air), respectively, ΣM_s is the sum of solid masses (balloon envelope and payload), and f is the free lift. Getting off the ground requires a positive free lift or excess gas of generally 15–20% of the total $M_s(1 + f)$. Because of the exponential decrease of pressure with altitude, the balloon expands continuously in volume during the ascent, until it reaches its float altitude. While reaching this level the excess gas corresponding to the free lift has to be evacuated or else retained by a high-strength material – otherwise the balloon bursts.

In one type of balloon, the zero-pressure, large open ducts at the base of the envelope vent the excess gas, so that the

Figure 1 Zero-pressure balloon of 2 000 000 m³ at float altitude. The excess gas is vented by seven open ducts at the bottom of the envelope. © NASA.

pressure differential from inside and to outside remains small (Figure 1). In the other, the superpressure sealed balloon, the excess gas converts into a differential pressure that is retained by the high strength, and thus necessarily heavy material.

Since the strength on the envelope is very small, a zero-pressure balloon can be manufactured in light 20–40 μm thin polyethylene material. Its volume can be as large as required – up to 2 million m³ for carrying a load of several hundred kilograms up to 40 km. However, there are two limitations: launch operations and flight duration. Though efficient methods (crane or auxiliary balloon) have been developed to keep the payload off the ground at liftoff, the size of the balloon, which is only partially inflated at ground (300 m high for the largest balloons), makes a launch very sensitive to surface wind. The maximum acceptable wind speed is generally 2–3 m s⁻¹ at 50 m height, or even at 200 m for the largest balloons, which sometimes means waiting for weeks for the right conditions. The second limitation is the duration of the flight. The cooling at sunset makes the balloon to contract and descend, and this can be counteracted only by an irreversible drop of ballast. The duration of the flight is thus limited by the amount of ballast, which must be carried only at the expense of the scientific payload. Zero-pressure balloon flights are generally limited to few hours. However, long-duration cruises of up to 4–5 days across the Atlantic or the Soviet Union have been effected through carrying a large amount of ballast or alternatively by replacing the solid ballast by a reservoir of liquid helium to compensate the loss of gas. Longer flights have also been achieved in the specific case of permanent day or night in polar areas, thus requiring little dropping of ballast. Taking advantage of such conditions, zero-pressure circumnavigations of 2–3 weeks (1 month in 2002) have been achieved over Antarctica by NASA in the summer and also by the Japanese.

Long-duration flights generally require totally different approaches. Two successful ideas, both currently in use, have been suggested: superpressure balloons and Infrared Montgolfier. The first promoted by Lally at NCAR in the 1960s is derived from a concept of small spherical paper balloons used by the Japanese during World War II. The superpressure balloon is a sealed sphere in which the excess gas corresponding to the free lift converts into overpressure. The pressure increases during daytime solar heating and decreases with the cooling at night. Since the volume and the mass of the system are constant, the balloon flies at a constant density (isopycnic) level. It remains aloft until leakage reduces the overpressure to zero in the night cold, when the balloon irreversibly drops. The system is limited by the thickness and thus the weight of the material – which is generally polyester fabric or polyethylene composite – that is required to maintain the overpressure. Since the stress of the envelope increases with the balloon's radius, the size of a superpressure balloon for a given material is limited to the volume at which the balloon can carry its own unladed weight. For a spherical balloon of polyester, the limit is around 12 m diameter, allowing a payload of 30 kg at around 19 km altitude.

To overcome this limitation, a new design has been suggested in France (CNES Stratospheric Super-Pressure Balloons), in the United States (NASA Ultra Long Duration Balloons (ULDB)), and also in Japan, which consists of a 'pumpkin-shaped' balloon. In this design, Kevlar tendons take the meridional stress while the longitudinal stress is reduced by the small local radius of the pumpkin lobes or gores, which allows a reduction in the density of the balloon material. Though this solution seems promising, there are technical difficulties still to be overcome, particularly in the arrangement between the tendons and the envelope when reaching float altitude. Though a successful 3-month flight was achieved in 1992 by CNES in South Africa, other attempts have failed. The same happened at NASA with its ULDB Program started in 1998. Although some test flights have been successful in Antarctica during the polar day, all other attempts in Australia or Kiruna have failed. However, there is no doubt that once these problems are solved, the pumpkin shape could offer a unique opportunity for suborbital long circumnavigations of large payloads at high altitude for astronomy and the remote observation of the atmosphere.

A totally different concept, suggested by the present author and Hauchecorne in the late 1970s, is the use of a hot-air balloon heated at night by the Earth's thermal emission, and therefore named Infrared Montgolfier (MIR). This is achieved by adding a very low thermal-emission aluminum layer to the upper half of the infrared absorbing polyester envelope, thus preventing the balloon from radiating toward space, the lower half being in transparent polyethylene. In this arrangement, the temperature differential of 20–30 °C between the air inside the balloon and that ambient air in the cold stratosphere keeps the MIR stable at night. The extra lift provided by solar heating during daytime makes the balloon ascend and thus purge a large part of the lifting gas. But since this gas is air, it can be replaced during the evening descent by simply keeping open a large mouth at the bottom of the balloon. The system is thus reversible. The only limitation is during flying over very cold and low-emissive clouds, such as high-altitude anvils in tropical regions, which reduces the temperature differential between the inside and outside by a few degrees, which is not

enough to keep the balloon aloft for the whole night. In its present design, the MIR of 45 000 m³ volume carries 60 kg at 28 km during daytime and between 18 and 24 km at night, depending on the cloud cover, for an average duration of 3 weeks, with a record flight of 2 months in the tropics.

The various techniques above could also be combined. An example occurred in the recent record manned flight around the world, which used a helium balloon on top of a hot-air system, both covered by an aluminized layer to reduce the radiative heat loss and carrying a ballast of propane to feed a burner in case of major cooling.

Current Scientific Balloon Systems and Their Use

Based on the above concepts, a variety of balloon systems are available to the scientist wanting to study the Earth's, or another planet's atmosphere, the characteristics and performances of which are summarized in Table 1. They are all described below from the point of view of the user, together with examples of their application.

Open Zero-Pressure Balloons

The most commonly used scientific balloon is the zero-pressure balloon (Figure 2). Its volume varies from 50 000 m³ to 2 Mm³ or more, which can carry between 100 and 2000 kg (the record is 3600 kg) between 25 and 40 km (the record is 42 km); see Figure 3. It is equipped with powerful telemetry and remote control transmissions of up to 500 bps. For many purposes, the gondola is stabilized or oriented toward the Sun or an astronomical object, or even stabilizes with respect to a magnetic or geographic heading. In most applications, flight is limited to within the telemetry range from the control station of 300–400 km that is for duration of a few hours, though it can be extended by using a downrange receiving station. The size of the balloon (up to 300 m high at liftoff), as well as the weight of the payload, requires the use of mobile crane or else auxiliary balloons to keep the gondola off the ground during the launch operation, which has to be performed by a well-trained team. The descent of the payload for recovery below one or several parachutes terminates the flight. However, and this is of great interest for atmospheric research, the ascent or descent speed and altitude of the balloon can also be adjusted by alternately

Table 1 Performances of scientific balloons

Balloon	Volume (m ³)	Payload (kg)	Altitude (km)	Duration
Zero pressure	5000–2 000 000	50–2000	25–40	Hours–days
Pressurized sphere	50–600	2–20	12–19	Weeks–months
Pressurized tracers	3–8	2–3	1–5	Weeks
Pressurized pumpkin	1 000 000	1000	35	(Goal 100 days)
Infrared Montgolfier	45 000	60	27 (day) 18 (night)	Weeks–months

valving the gas and dropping the ballast. This facility is now in common use for studying a specific layer, e.g., stratospheric clouds in polar areas, or setting a slow descent speed across the whole stratosphere for air sampling or chemical analysis.

In the United States, balloons manufactured by Raven/Aerostar are operated by the NASA Columbia Scientific Balloon Facility (25 flights per year, with payloads of up to 2000 kg) at Palestine, Texas; Fort Sumner, New Mexico; McMurdo, Antarctica; Alice Spring, Australia; and Kiruna, Sweden. In France, they are manufactured by Zodiac Espace and operated by the CNES space agency at the Centre de Lancement de Ballons at Aire sur l'Adour or Gap in the summer in southern France (20 flights per year, with maximum payloads of 500 kg for safety reasons) as well as in Kiruna, Sweden. Several other countries are also conducting balloon programs on their own or in cooperation with the United States and France: Japan, India, China, Canada, Australia, Norway, Sweden, Italy, Brazil, Argentina, and Indonesia. The Soviet Union has had an extensive program in the past, including 4- to 5-day flights from European Russia to Siberia in the winter and from Kamchatka to the Urals in the summer, but this has been suspended for the moment.

Depending on scientific objectives, both NASA and CNES frequently carry out series of balloon launches at remote sites at

all latitudes in Canada, Brazil, Australia, Alaska, Sweden, Antarctica, etc. Among others, recent examples are the series of winter campaigns conducted since 1990 by the CNES for the European Commission at the Swedish ESRANGE facility at Kiruna for studying stratospheric ozone depletion; those included THESEO-SOLVE in the winter of 2000, which involved both CNES and NASA.

The use of zero-pressure balloons in atmospheric science is twofold: (1) for the remote observation from the float level of the vertical profile of chemical species by techniques similar to that in use from orbit; (2) for *in situ* measurement, during ascent or slow descent, of aerosols, stratospheric clouds particles, tracer gases, and chemical species by a variety of techniques close to those in use in the laboratory. Remote sensing techniques include absorption measurements in the UV, visible, and infrared regions by solar, star, or lunar occultation, and emission techniques in the IR and microwave wavelengths. Most of the atmospheric instruments subsequently placed in orbit, such as the ATMOS Fourier Transform Spectrometer on the Space Shuttle, the Microwave Limb Sounder onboard the NASA Upper Air Research Satellite, or the MIPAS Fourier Transform Spectrometer on the ESA ENVISAT satellite, have been flown first on balloons. Besides the new science which could be derived a long time ahead from the long lead time

Figure 4 Small, light, zero-pressure balloon of 10 000 m³ ready for launch at the ESRANGE facility at Kiruna in northern Sweden during the Ozone THESEO-SOLVE campaign in February 2000. development of a space project, the advantage is the advanced maturity of the retrieval algorithms as well as later, the validation of the measurements from space by direct comparison with collocated balloon observations.

But the unique contribution of balloons to atmospheric science is the *in situ* measurement of a number of parameters and species, and their altitude and time variations, which cannot be done by other methods, particularly in the stratosphere. Examples include the profiles of the organic chlorine and bromine species (chlorofluorocarbons and halons) responsible for the destruction of ozone; the profile of OH, the hydroxyl radical involved in many chemical cycles; the composition of the crystals of polar stratospheric clouds, which triggers the ozone loss process in polar areas; and high-resolution profiles of long-lived species or tracers needed to understand transport processes. The list of instruments flown includes mass spectrometers, gas chromatographs, samplers, fluorescence-resonance chemical reactors, aerosols, and condensation nuclei counters, tunable diode lasers associated to multiple path-length cells, etc.

Light, Small, Zero-Pressure Balloons

Large zero-pressure balloons as described above are powerful tools, but since they are extremely sensitive to surface wind, and hence cannot often be launched when required, they are difficult to use in atmospheric science. In addition, their operation needs heavy equipment and large facilities, while finally their relatively high cost does not allow them to be flown as frequently as is desirable for recording atmospheric variability. An alternative approach, explored during recent years by CNES, is the reduction of the size of the balloons (Figure 4). This is achieved by using lighter material, 16 μm and more recently 12 μm thick, but reinforced at the gores assembly, and also by reducing dramatically the weight of the payload by applying miniaturization techniques to scientific instruments as well as to operational subsystems. Finally, launch techniques have also been revised. The payloads are

designed to be dragged, perhaps on a sledge, on the launch pad, thus not requiring auxiliary balloons or a crane. In such design, a 10 000 m³ balloon carrying 100 kg of apparatus at 32 km could be launched in a surface wind at up to 7 ms⁻¹ (30 km h⁻¹) that is in most meteorological conditions. This flexibility meets a variety of scientific requirements such as those imposed by sunset or sunrise, the presence of polar stratospheric clouds, satellite overpass, tropical storms, etc.

A number of lightweight atmospheric instruments in the 5–20 kg range have been developed in Europe and in the United States for use with these smaller, lighter balloons: UV-visible solar or moon occultation spectrometers, tunable diode lasers, air samplers, aerosol counters, gas chromatographs, and resonance fluorescence reactors, measuring a broad range of chemical species. Such instruments are frequently flown together on the same balloon from unprepared or wind-exposed ranges, in order to study polar ozone chemistry, stratospheric clouds, tropical convection, seasonal and diurnal cycles, long-term trends, satellite validations, etc. However, for safety and programmatic reasons, CNES small balloon and long duration MIR and super-pressure balloon flights are no more feasible preventing the continuation of the above successful projects. It is hoped that they could restart in the future.

Tethered Balloons

Basically, tethered balloons are open balloons that are only a little pressurized, the excess gas being vented through a valve. Though the concept is simple, tethered balloons have been of little use in atmospheric research except in the lowermost boundary layer. Attempts to build permanent atmospheric observatories in the lower stratosphere around 20 km in France in the 1980s, using newly available Kevlar cables, failed totally,

mainly because of gusty winds but also because of air-safety constraints. The use of tethered balloons seems thus to be limited to the lowermost 1–2 km levels in light wind and in areas with little air traffic. However, a promising system for studying the sea–air interface in remote oceanic regions is the drifting balloon attached to a floating guide rope as tested in 2000 by the CNES in the tropical Atlantic.

Superpressure Balloons

As noted earlier, superpressure balloons were developed originally in the United States at NCAR for studying the meteorology of the upper troposphere. They were spherical balloons of 43 µm thick polyester and 2.70 m diameter, able to carry a 2.5 kg payload at 200 hPa (12 km). In the late 1960s and early 1970s, more than 400 balloons were flown by NCAR within a GHOST project from New Zealand in the frame of the international Global Atmospheric Research Program. In addition, another 400 of similar size were flown by the French from South America using a dedicated satellite, EOLE, to track them with a new receiving system at the origin of the ARGOS satellite data collection in broad use in ballooning nowadays. On both projects, the average flight duration was around 3 months, with a record of 1.5 years.

In order to meet the scientific demand, superpressure balloon programs have evolved in two directions: small tracer balloons in the planetary boundary layer and relatively large ones for studying transport in the lower stratosphere. The first type, with the payload mounted inside the envelope to protect the electronics from rainfall (Figure 5) were, for example, flown for several weeks in the 1980s over the Indian Ocean for investigating the atmospheric circulation associated to the monsoon. The experiment was repeated in 2000 in India,

Figure 7 Artist's view of the ULDB pumpkin superpressure balloon at float. ULDB, Ultra Long Duration Balloons. © NASA.

during an INDOEX international project, as well as in Argentina, and more recently in the Indian Ocean, West Africa, and the Mediterranean.

The second type of balloon was the large spherical one flown in the lower stratosphere (Figure 6). But as explained earlier, and shown for example by the unsuccessful attempt by NCAR in the 1980s to develop a 24 m diameter balloon to carry a dropsondes package at 24 km, these balloons are at the limit of technology. The largest system currently existing at CNES is a 12 m diameter balloon carrying a 30 kg payload at

19 km for studying the dynamics of the winter Antarctic stratosphere.

Ultra Long Duration Balloons

Unless a new, high-strength material appears in the future, the size and therefore the altitude of spherical superpressure balloons will be limited. The only way to overcome the limit is to change completely the architecture of the balloon and adopt a pumpkin shape (Figure 7). A large pumpkin balloon

Figure 8 (a) Test flight of MIR 5600 m³ prototype in the early 1980s at Pretoria, South Africa. © CNES. (b) Release of an aluminized 45 000 m³ MIR at Kiruna in February 2000 for studying ozone depletion in the winter Arctic stratosphere. After 18 days the flight was terminated and the payload recovered in Russia. © CNES. (c) Release of an aluminized 45 000 m³ MIR in Brazil in February 2001. The balloon flew for 34 days and two circumnavigations over the tropics before recovery in northern Argentina. © CNES.

of 58 m diameter for carrying 1.6 tons at 33.5 km for 100 days is under development at NASA since 1998. Though a few test flights of smaller balloons have performed successfully in Antarctica and in the Arctic, the vehicle is still not fully operational illustrating the difficulty of the project. However, the program is continuing. There is no doubt that when successful ULDBs, renamed recently as superpressure balloons, will be powerful tools in enabling atmospheric observation to be made by new passive or active remote sensing instruments long before such instruments are able to be placed in orbit.

Infrared Montgolfier

Because of the smaller lift of hot air compared with hydrogen or helium, the MIR ([Figure 8](#)) requires a larger volume than gas balloons for the same payload. But, in turn, it is a zero-pressure balloon and so the stress applied on the material is weak. The MIR is thus a robust balloon whose duration is limited only by the capacity to fly over very low-emitting high-altitude clouds. In its present design of 45 000 m³ volume, the MIR available at CNES in France can carry a payload of 60 kg for several weeks around the world. It has been flown successfully for more than 2 months at the tropics and for up to 3 weeks in the Arctic in the winter and spring, where the limitation comes more from the restriction of flights to north of 55° N for air safety reasons, than from adverse meteorology.

Taking advantage of the diurnal change of altitude from 18 to 20 km during nighttime to 27–28 km during the day, a number of atmospheric observations could be performed, ranging from passive or active remote sensing by solar occultation or lidar, to profiling *in situ* by a variety of techniques. In its current design, the MIR is fully operational. However, further tests of thinner and lighter balloon material are in progress for extending the duration of flight. When successful, and together with new, powerful low-orbit satellite transmissions, it will be a unique tool for combining *in situ* and remote measurements for studying several processes of importance at work in the global stratosphere and climate.

Planetary Ballooning

Though the composition of their atmospheres is different than that of the Earth, several planets in the solar system could also

be explored by balloon systems. Of particular interest are those totally covered by clouds and thus where the surface is invisible from space, such as Venus and Titan. But this could apply also to the study of the meteorology and the surface of Mars, where a balloon could help observe a variety of landscapes with a single station. Several concepts have been studied in the past and sometimes fully developed and tested in France, the United States, and the Soviet Union. Among them, the most advanced space mission projects were a heavy, 10 m diameter Kevlar cloth superpressure balloon for Venus and a thin 6 μ m superpressure balloon for Mars landing at night and dragging a long instrumented guide rope on the surface. Unfortunately and for various technical and programmatic reasons, they have been all canceled but one: a highly successful Teflon balloon designed and flown by the Russian Institute for Cosmic Research (IKI) in the atmosphere of Venus during the Russian–US–French VEGA mission in 1985. Teflon was chosen instead of polyester because of the presence of sulfuric acid clouds in the Venusian atmosphere, resulting in a new concept of sealed, superpressurized, and slowly expandable balloon. Injected on the night side of the planet at 53 km, in the high-altitude 4-day circulation, the balloon performed beautifully for 48 h as expected, allowing the observation of pressure, wind, and temperature change along a night–day transition and for the full following day. Though this success still remains unique, several concepts of zero pressure, super pressure, and Montgolfier autonomous systems, named Aerobots for Robotic Balloons, continue under study in the United States and France, for further planetary exploration missions.

This article is reproduced from the previous edition, volume 4, pp 1438–1443, © 2003, Elsevier Ltd.

Introduction

The need to collect real-time meteorological data to be used in forecasting is commonly accepted as important to the protection of life and property. Indeed, one can find observers or packages of automated instruments tasked with collection of meteorological data spread, often densely, across many countries of the world. Unfortunately, the world's oceans are much less densely populated with observing systems. It is difficult to acquire meteorological data at sea. Observers aboard ships are sometimes too busy to take observations when they are most needed. Satellite sensors can be foiled by clouds. The best solution for collecting data at sea is from buoys, either moored or drifting. This article will discuss the types of buoys often used, what data are collected or might be collected, and the advantages and disadvantages of the general buoy types. Because of the author's experience, the article will emphasize the systems used by the National Oceanic and Atmospheric Administration, National Weather Service, National Data Buoy Center (NDBC) of the United States of America.

Purpose and Types

A number of nations collect meteorological data from moored buoys in support of their warning and forecast missions. These include the United States and Canada, which have large networks of moored buoys; the United Kingdom and France, whose networks are somewhat smaller; and nations like Japan, Korea, Australia, New Zealand, and India, which have even smaller networks. In addition, most of these nations, as well as South Africa, Brazil, Germany, Ireland, and The Netherlands, have used drifting buoys in their data collection efforts. Buoys are used in the open ocean, in inland seas, and in major seaways. They are particularly important to forecasters on the eastern boundaries of the oceans and where tropical and extratropical storms are common. Often, data from a buoy are important in the proper forecasting of storms forming over the oceans. Buoy data sometimes provide surface pressure and wind data indicating strengthening 12–18 h before satellite imagery. It is unfortunate that these data are so scarce compared to data from stations on land.

Generally, there are two types of buoys, moored and drifting. A discussion of the types of buoys in each category is appropriate.

Moored Buoys

Hulls

There has been considerable evolution of moored buoy types, which started quite large both to ensure stability at sea and to house the large numbers of batteries, a diesel generator or two, and diesel tanks needed to power the sensors and transmitters.

Break throughs in solar power technology and microelectronics have resulted in the size of buoys being greatly reduced and their capabilities being considerably enhanced.

Stability is an important characteristic of moored buoys. They must provide a stable platform for the acquisition of data, be able to withstand severe sea conditions without capsizing, and protect the electronics needed to control the collection, processing, and transmission of the data. Early buoys were often quite large, first 12 m in diameter, then 10 m. These steel buoys were survivable and had considerable room for the systems required for data collection in the early 1970s. Because they were large, though, they were expensive and difficult to deploy and recover. Eventually, an alternative was found that provided good survivability and adequate space, especially after improvements in solar power, instrumentation, and communications allowed for significant reductions in power requirements. That alternative was a boat-shaped aluminum hull, called a NOMAD when it was developed by the US Navy. It is the buoy hull now often used by NDBC and the Canadian Atmospheric Environment Service at their deep ocean stations. With its mooring attached at the bow, the buoy tends to align itself with the direction of the waves, making it much more survivable in high, steep waves. The highest significant wave height ever measured by an NDBC NOMAD buoy was 16.9 m, measured in the north-east Pacific Ocean. The significant wave height is the average of the highest 1/3 of waves. According to a generally accepted rule of thumb, the highest waves in a storm can be twice the significant wave height, meaning that the buoy probably survived waves as high as 30 m or more.

The same improvements that allowed for the development of NOMAD as a replacement for the huge discus buoys in the deep ocean encouraged the development of smaller buoys for both meteorological and oceanographic use. One of the principal innovators in buoy technology was the Woods Hole Oceanographic Institution in Woods Hole, Massachusetts, USA. Their development of an aluminum discus buoy hull of 3 m diameter made possible the collection of data from networks of moored buoys. The 3 m buoy and its derivatives, while not inexpensive, are considerably more economical than either the large discus buoys or NOMADS. A direct descendent of the Woods Hole 3 m buoy is used extensively in the United States and Canadian networks. A few 12 m and 10 m buoys can still be found operationally deployed, but the majority of buoys now used for the collection of meteorological data are either NOMADS or 3 m discus buoys. Examples of those buoys may be seen on the NDBC web site, (<http://www.ndbc.noaa.gov>).

Not all buoys used for meteorological data collection are exactly like those used in the United States and Canada. One considerable network, deployed in the tropical Pacific and Atlantic oceans by the US National Oceanic and Atmospheric Administration's Pacific Marine Environmental Laboratory, in

conjunction with French and Japanese agencies, uses a toroid buoy. These fiberglass-wrapped foam hulls are less expensive than aluminum hulls, but they are also less capable buoys. In fact, their primary purpose is to collect oceanographic data, with only limited meteorological data collection capabilities. With their moorings containing oceanographic instrumentation, the buoys are replaced each year. This is necessary for good oceanographic data collection, but it would be considered unduly costly for long-term collection of meteorological data.

Other networks use a variety of buoy hull types that they have determined to be best suited to their needs. The buoys used in the United Kingdom, Japan, and Korea are quite different from those of the United States and Canada, but they perform very well for their weather services.

Moorings

A mooring is a system comprising a chain, cable, and/or rope and an anchor of some type that keeps the moored buoy on station. One of the most significant differences between moored buoys intended to collect meteorological data and those intended for oceanographic investigations is the mooring they use. As mentioned previously, oceanographic data collection buoys are replaced frequently, at least in comparison with meteorological buoys. Their oceanographic sensors are susceptible to fouling and, therefore, must be changed or cleaned periodically. Meteorological buoys are often a part of an operational observing network, and frequent replacement of buoys is much too expensive. Both the electronic and the mechanical systems used on the buoys must therefore be long-lived. Moorings are an important component of buoy longevity.

Considerable effort has been put into mooring design, modeling, and field testing in order to develop moorings that will provide a simple, long-term, deep water capability at reasonable cost. Designers of moorings for environmental observations had the advantage that they did not need the tight watch circle (the circle around the buoy's anchor within which the buoy drifts) required of navigation buoys marking a channel. The watch circle for a meteorological buoy was able to be wider because of the consistency of meteorological data over a relatively few miles of ocean. Because of that flexibility, the design of the mooring system was more open to innovation. Two general types of moorings are typically used for meteorological buoys: semi-taut and inverse catenary. Semi-taut moorings are common in shallow water and are most often made either of all chain, in waters up to about 90 m deep, or a combination of chain and, typically, nylon line of 5 cm or more in diameter. Semi-taut moorings using chain and nylon are used in water depths generally from 60 to 600 m. They consist of a length of chain immediately under the buoy, then nylon line, followed by another length of chain attached to the anchor. Semi-taut moorings involving nylon line are probably the most difficult to service, because they are often under tension at sea, essentially becoming taut moorings.

In an effort to design a mooring that allowed easier servicing or replacement of a buoy, NDBC developed its two types of inverse catenary moorings. These moorings have been used successfully in water depths as great as 6000 m and are routinely used in depths greater than 5000 m. The

mooring consists of chain immediately under the buoy; then nylon as in the taut mooring; then at a design depth, often in the range of 500–700 m, a length of polypropylene line or glass balls is inserted; then more nylon line to the bottom where it connects with chain and the anchor. The purpose of the polypropylene rope or glass balls is to provide a buoyant section in the mooring. This serves two purposes. First, it allows for some error in the expected depth of water. Should the anchor settle in water deeper than intended, the mooring will have enough excess length to allow for a successful deployment. More important is the isolation of the lower portions of the mooring from the buoy's motions. Mooring failures associated with wear most often happen where two hard components, such as chain links or chain and shackles come into contact with each other. In the upper mooring, there is considerable movement associated with the buoy's motions. That is not considered a problem, since the upper chain can be inspected when the buoy is serviced and replaced as necessary. Since inverse catenary moorings are almost never retrieved, that is not the case with the chain at the lower end of the mooring, in as much as 6000 m of water. The buoyant section of the mooring successfully isolates the lower mooring so it is not affected by buoy motion, reducing wear on the chain and other hard components at or near the sea bottom. An inverse catenary mooring was once recovered by the NDBC after having been deployed for nearly ten years. It was found that the lower portions of the mooring suffered almost no wear and that the nylon rope had retained nearly its design breaking strength.

Drifting Buoys

Drifting buoys, as the name implies, are those that move with the winds and currents in the ocean. Some, when deployed with drogues, are Lagrangian drifters, allowing ocean current speed and direction to be derived from their positions over time. Many are deployed without drogues, making them less useful in the determination of circulation patterns. Because drifting buoys can easily be deployed by ship or aircraft, they are often used in remote ocean areas for some basic meteorological data collection. Because they are considerably less expensive than moored buoys, they are also used in lieu of or to supplement moored buoy networks.

There are two types of drifting buoys most widely used today. The first, the FGGE (First Global GARP Experiment) buoy was extensively used in the Tropical Ocean and Global Atmosphere (TOGA) Research Program. These buoys were generally cylindrical, 3.7 m in length, and with a floatation collar at the waterline. The FGGE buoys have approximately 1.5 m of their length above the waterline. The second type of drifting buoy is the Surface Velocity Profiler – Barometer (SVP-B). These buoys are spheres on the order of 41 cm in diameter with a barometer port that stands approximately half the buoy's diameter above its top surface. They were designed to be Lagrangian drifters (SVP) and have been modified to provide some meteorological data (SVP-B).

Drifting buoys are packaged for deployment either from ships or from aircraft. In both cases, they are transported in containers that will come apart when soaked in sea water. This allows a sailor to simply drop the drifting buoy over the side of

the ship or an aircraft crewman to deploy it from the plane. For delivery by air, the drifting buoys are, of course, fitted with a parachute to ensure they survive the fall into the ocean.

Measurements

Moored Buoys

Moored buoys are important systems for maintaining weather and sea watch for warning and forecast updates. They provide sea truth for forecast model initialization and verification, warning and forecast verification, and radar and satellite data validation and calibration.

There is both consistency and variability in the measurements made on moored buoys. With few exceptions, wind speed, gust, and direction, atmospheric pressure, and air temperature are collected; this is a consistent feature among nearly all national programs. Wind and pressure data are considered important enough by NDBC that they have redundant sensors to increase the data return. It is also important that the buoys report their location in order to ensure that the buoy is not adrift. Other data often collected include relative humidity; solar radiation; precipitation (amount and/or rate); oceanographic measurements, including wave height, period, energy spectral information, and, sometimes, direction; sea surface temperature; and ocean current (point or profile). In these lie the variations among the data collection networks. Different nations have identified different data priorities.

Drifting Buoys

Drifting buoys provide a more global capability for acquiring and reporting environmental observations. They are useful for scientific and climate programs, weather forecasting, and hurricane tracking.

Drifting buoys have considerably less capability than moored buoys, principally because of their size and limited power. All drifting buoys report their location. This was what they were originally designed to report, so that their drift direction and rate might be calculated. The first drifting buoys to report meteorological data reported only atmospheric pressure and air and sea surface temperature. The size of these FGGE buoys, though, allowed the addition of a Savonius Rotor to measure wind speed. After some design work and prototype testing, a wind fin and compass were added to provide wind direction. In some drifting buoys, accelerometers or other devices have been added to provide wave data.

The SVP-B was a logical result of the SVP. Oceanographers were able to adapt the SVP to add a barometer port above the buoy and a moisture filter to protect the barometer installed inside the buoy. As with the FGGE buoy, the SVP-B also collects sea surface temperature. This relatively inexpensive buoy has allowed the deployment of many more drifting buoys in the remote portions of the oceans. They have been the mainstay of international buoy programs in the South Atlantic and Indian Oceans, as well as in the Arctic and Antarctic. Even with only pressure data reported, there have been several studies performed by the South African Weather Bureau that have shown the value of even just a few pressure data points

from drifting buoys in improving forecasts during the winter storm season. Development of the SVP-B continues. There are efforts to add wind speed measurement capability to the buoy using underwater acoustic sensors, hydrophones that measure the sound of bubbles made by the wind. Wind direction might be measured using a wind fin on the barometer port. The potential for wind measurement from the SVP-B is an exciting prospect.

Data Transmission and Distribution

Data from buoys are useful for warnings and forecasts only if those data are available in real time to the forecasters. It is important that the data be transmitted frequently and distributed immediately.

Moored Buoys

While moored buoys are designed to report via either geostationary or polar orbiting satellites, most moored buoy networks use the geostationary satellites to transmit their data to shore. In North America, the satellites used are the Geostationary Operational Environmental Satellites, one in the 'east' and one in the 'west'. European data are transmitted via Meteosat, and Asian data are transmitted via the Japanese and Indian satellites. Data are typically transmitted hourly through the satellites to a ground station. The data are then quality controlled using automated algorithms and the good data are distributed through the Global Telecommunications System to forecasters around the world. Some networks distribute raw data without attempts at quality control. In those cases, the forecasters must understand that the data have to be compared with other available information before they can be accepted as correct.

Drifting Buoys

Drifting buoys may be deployed or may drift outside the footprint of the geostationary satellites. Together with their limited power, this means that they must often depend on the polar orbiting satellites for data transmission. Data from drifting buoys are typically transmitted to the Polar Orbiting Environmental Satellites as they pass overhead. The data are stored until the satellite passes in 'sight' of one of the receiving stations around the world. After being downloaded, the data are quality checked using automated algorithms and released on the Global Telecommunications System. Raw data can also be acquired on Local User Terminals and used immediately by a forecaster with access to that terminal.

Advantages and Disadvantages of Moored and Drifting Buoys

As might be expected, the advantages of moored buoys are often the disadvantages of drifting buoys, and vice versa. In designing a network for marine meteorological measurement, these advantages and disadvantages must be weighed. In some cases, a moored buoy network is clearly preferable. Sometimes deployment of drifting buoys is more desirable. A mixture of moored and drifting buoys can provide a solution to some needs.

Moored Buoys

Advantages

Moored buoys offer some distinct advantages over drifting buoys. Most importantly, they provide high-quality, real-time data in scheduled data messages when reporting via geostationary satellites. They are a mature technology, so there are few failures because of unproven technology; they have demonstrated their performance over years of use and millions of data messages per year. Moored buoys have, on average, a 3-year lifetime before they have to be replaced. The buoy hulls used by most weather services have virtually unlimited lifetimes, since they can be recovered and refurbished many times. Some of the NOMAD buoys being used by NDBC, for example, were built in the 1950s and are still serviceable. Moored buoys are at fixed locations, allowing the accumulation of a long time-series of data from a constant location, important for understanding climate. Finally, the buoys typically have enough reserve buoyancy and power to allow measurement capability to be added.

Disadvantages

The primary disadvantage of moored buoys is their cost to build and operate. A network of moored buoys is an expensive proposition, although when a per-measurement view is taken, they are often competitive with any other buoy system. The advantage that moored buoys offer by being in a fixed location can also be seen as a disadvantage, since they are designed to be unable to drift with currents. Because of their size, moored buoys require significant deployment resources and their deployments must be well planned. This means that a moored buoy cannot usually be deployed in front of a major storm. Rapid response is not an option.

Drifting Buoys

Advantages

A principal advantage of drifting buoys is their relative low cost, which allows them to be used as an expendable system, although some can be recovered and refurbished. They are also very valuable in remote ocean areas, where servicing a buoy is difficult and expensive. The drifting buoys now in use have a 1- to 2- year lifetime, allowing them to provide data of acceptable quality from a long track across the ocean. Their size and packaging allow the use of many different types of deployment resources. This also means that they can be used for rapid response to developing storms, such as hurricanes, or deployed in arrays of flexible design. Some drifting buoys can also be moored, making them a very flexible buoy system. Finally, they can be drogued to act as Lagrangian drifters.

Disadvantages

Because drifting buoys report through the polar orbiting satellites, their data are not provided on a schedule. This results in some of the data not being available in real time, reducing the usefulness of the data to operational forecasters. The buoys are not in fixed locations, so they do not provide useful climate data for certain applications. There are also trade-offs in data

quality because of the size of the buoys and their intimate contact with the ocean surface. Compared to moored buoys, some drifting buoys have a relatively short life. Finally, because of their size, it is difficult to add sensors and increase their capabilities.

Conclusions

Buoys provide data from a significantly under-measured portion of the Earth's surface. Their data are critical to marine warnings and forecasts, as well as to forecasts over considerable portions of the continents, often many hundreds of miles from the coast. The importance of meteorological data from buoys is recognized worldwide, with a number of nations maintaining networks of moored buoys or deploying drifting buoys in considerable numbers. Buoys are dependable, proven technology.

Introduction

Although kites have been used both for practical purposes and for entertainment for thousands of years, their use for atmospheric research dates back only two hundred years or so. Information derived from kite-borne measurements comprised our first real systematic study of the free atmosphere. The use of kites for atmospheric research peaked sharply around the beginning of the twentieth century, with near-daily observations being made at many observatories throughout the world. Techniques developed during those early times provided a blueprint for subsequent research using data gathered from balloons, airplanes, and, ultimately, satellites. The use of kite-borne meteorological data collection has been renewed during the past decade and currently occupies a welldefined niche in meteorological research. There are a number of advantages provided by having an instrumented kite flying for extended periods a few kilometers above the Earth's surface that cannot be provided by any other means. The full height range of this region is difficult to access more or less continuously by any other technique.

A Brief History of Atmospheric Research Using Kites

Professor Alexander Wilson and his student Thomas Melville, both of the University of Edinburgh, Scotland appear to have initiated the first kite-borne atmospheric measurements in 1749. Wilson and Melville launched a string of paper kites on a single tether, each kite carrying a thermometer attached to its tail. All of the thermometers were enclosed in 'bushy tassels of paper' to insure a soft landing, and were released from their respective tails by smoldering 'fuses'. If gathered quickly after their recovery, the thermometers yielded a rough estimate of the temperature profile up to heights where the highest kite was observed 'disappearing at times among the white summer clouds'.

These early temperature 'profiling' measurements in Scotland were followed in 1752 in Philadelphia by the well-known atmospheric electricity experiment of Ben Franklin. No further kite-borne atmospheric experiments were reported for almost seventy years, until Captain Parry on his second Arctic expedition to Igloolik in the Canadian Arctic in 1822 attached a thermometer to a paper kite, which achieved an altitude of about 130 m. Although he was attempting to measure the lapse rate, he found that the temperature was relatively constant. In a similar measurement made at the same location in 1836–37, however, Admiral Back on HMS *Terror* raised a kite to three times that altitude from the deck of his frozen-in ship, and detected a 5.5 degree (Celsius) temperature decrease.

The first successful measurement of cloud-base heights was made some three years later by meteorologist J. P. Espy, a member of the Franklin Kite Club in Philadelphia. While Espy

only intended to verify his theoretical calculations of cloud-base heights, he also detected strong updrafts just below the clouds as well as evidence of an electrically charged atmosphere. These successes were followed in 1876 in New Jersey by Cleveland Abbe, who flew a kite to determine the depth of the sea breeze.

Early measurements of horizontal wind profiles were begun in the mid-1880s in England by E. Douglas Archibald. Archibald is considered by many to be the first person to make systematic use of kites for atmospheric measurements. During these early measurements, he used a series of tandem-connected kites to profile the wind to over 395 m. Archibald used a self-recording kite-borne anemometer, and flew his kites on a piano-wire tether, following the suggestion of Sir William Thompson (Lord Kelvin).

Following Archibald, most early meteorological kites were flown on piano-wire tethers. Piano-wire provided greater strength per unit weight and diameter than any other tether. While piano-wire tethers enabled systematic measurements to altitudes of many kilometers, the use of a conducting tether proved to be quite dangerous. The danger arose from the fact that the atmosphere is strongly electrically charged, even under clear weather conditions, and the tether provided a convenient discharge path between the kite and the ground. At least one instance has been recorded in the scientific literature of the electrocution of an operator/technician flying a kite during a pending thunderstorm.

Actual measurements of the atmospheric electric field during this same era were made by Alexander McAdie at Blue Hill (Massachusetts, USA) and L. Weber at Breslau (Germany). These studies, which incorporated kite-borne electrometers, built on the pioneering work of Franklin and Espy.

On the basis of these early developments in kiteborne atmospheric research, a series of kite and balloon observatories were constructed during the waning years of the nineteenth century and the early part of the twentieth century. These observatories were dedicated primarily to systematically profiling winds, temperatures, humidity, and pressure to better understand the weather. The famous Blue Hill Observatory near Boston (a privately funded observatory built by A. Lawrence Rotch) played a major part in the development of meteorological kite technology. For example, it was from Blue Hill that W. A. Eddy in 1894 succeeded in launching the first recording thermograph. Eddy's success was followed a year later at the observatory by the launching of a recording meteorograph (temperature, pressure, and humidity). On a somewhat grander scale, the US Agricultural Department's Weather Bureau (predecessor to the US Weather Service) established 17 sites east of the Rocky Mountains beginning around 1898, where kites were flown on a daily basis (weather permitting) until 1933.

Additional outstanding contributions to scientific kite research were made around the turn of the century at a number of observatories in Europe, as well as from other groups around

the world. L. P. Teisserenc de Bort not only founded the Trappes Meteorological Observatory (kite and balloon studies) near Paris, but was exceedingly active in making balloon and kite-borne measurements in Hald (Denmark) and aboard ships in the North Sea. The Lindenberg Observatory near Berlin, which still exists today, was originally established by Professor R. Assman as an observatory for kite-borne measurements. In addition, a number of smaller facilities were established throughout England after the turn of the century. Data from these facilities added appreciably to a knowledge of atmospheric conditions over the British Isles. Other observatories were established in subsequent years in Russia, Egypt, and India, while extended campaigns using kites and balloons were made to such far-flung places as East Africa, the Bahamas, Java, and Antarctica. In support of the global scale of these activities, the International Conference on Aeronautics held in Paris in 1896, established 'international days' – usually the first Thursday of every month – to coordinate kite and balloon flights in all countries.

With regard to kite-borne observations from boats, Teisserenc de Bort (Trappes) and Lawrence Rotch (Blue Hill) cooperated in an observational program aboard Rotch's converted steam launch *Otaria*. These observations extended from the Azores to the Equator in the central Atlantic. Their ocean-going observations followed Rotch's initial trans-Atlantic voyage between Boston and England, during which he flew instrumented kites on five out of a possible eight days. During this period Professor Hergesell (Germany) also flew a kite from a launch owned by Count von Zeppelin on the Bodensee, and made atmospheric measurements from the *Princess Alice*, a yacht owned by the ruler of Monaco, in the Atlantic. The outstanding work of W. H. Dines (an early president of the Royal Meteorological Society) off the west coast of Scotland during 1898–1903 also provided strong impetus for the kites-from-boats technology and for studying the atmosphere over the ocean.

Although it is difficult at this point to determine the absolute level of activity in kite-borne atmospheric research during this early period, it is clear that essentially all of the detailed information on the first few kilometers of the atmosphere around the globe before 1930 was derived from kite-borne instruments. What is certain, however, is that well over one hundred publishing scientists were actively involved in this technology during the three to four decades centered on the turn of the century. During this period, tens of thousands of atmospheric kites were launched around the globe, from the Arctic to the Antarctic and from hundreds of locations on all of the remaining continents as well.

The development of both inexpensive balloonsondes and aircraft in the early 1930s was instrumental in the decline of the use of kites for atmospheric research. After about 1930, systematic atmospheric measurements by kites were viewed as too labor-intensive and expensive. M. W. Harrington, Chief of the US Weather Bureau in 1893, estimated the cost of a single kite-borne profile to ~ 4.5 km to be \$16, roughly \$320 in today's dollars. In addition, beginning in the early 1930s, kites were seen as impediments to the burgeoning aircraft activity.

With regard to the altitudes obtainable by meteorological kites, the Blue Hill Observatory prior to the turn of the century had an impressive multiyear record of lofting meteorological

kites with recording instruments to altitudes well in excess of 3 km. These altitudes were typically reached by connecting a series of separate kites along the same tether. Other observatories listed comparable heights during the same era. These accomplishments should be contrasted with the highest record height of 9740 m reported by the Lindenberg Observatory in 1919 using tandem kites.

The Current Status of Meteorological Research Using Kites

Renewed interest in the use of kites for atmospheric research has become apparent over the past decade or so. This interest has arisen primarily because of the inherent difficulty in making fine-scale, continuous, *in situ* measurements in the first few kilometers of the Earth's atmosphere. Available techniques, which include meteorological towers, tethered balloons, low-flying aircraft, and remote sensing systems (satellites and ground-based radar and lidars), all have significant restrictions. Towers do not extend far enough into the region to provide a number of important answers. Tethered balloons are typically limited to 1–2 km, and then only under light-to-moderate wind conditions. Low-flying aircraft are unable to examine small-scale features because of their speed, and there are obvious safety limitations involved in flying too low. Finally, remote sensing instruments are limited in height resolution and normally measure only specific quantities.

In contrast, present-day kite platforms offer a relatively inexpensive means of obtaining more-or-less continuous measurements of a large variety of critical quantities over a single site. Measured quantities include chemical constituents as well as atmospheric dynamics. Perhaps the best summary of the potential of kite-borne technology for atmospheric science is expressed by stating that it is virtually impossible to obtain continuous, high-resolution measurements of any atmospheric quantity for extended periods (i.e., for many hours) over a single location at altitudes greater than about 2 km by any other means.

Present-day Kite Platforms, Tethers, Winches, and Capstans

The current technology for kite-borne measurements is very similar to that used in the early days, except that present-day systems use state-of-the-art materials and the data-gathering instruments are more complex. Although a variety of kites have been used in current research, the kites used most often are of moderate aspect ratio, ram-air-filled parafoils designed for stability, portability, and reasonable payload capability at high elevation angles. (TALA kites have also been used successfully to measure wind speed at kite level by measuring the tension along the tether.) Parafoils have no rigid supporting structures, are easily transportable, and are typically constructed of nylon or Kevlar-strengthened Mylar with Kevlar or Spectra bridles. Kite sizes range from small kites of a few square meter areas for lofting light payloads, to larger payload systems having areas of 15–20 m². **Figure 1** shows a typical parafoil used in atmospheric studies.

Figure 1 Large parafoil kite used for atmospheric studies. Typically, the payload is attached some distance below the kite on a separate line attached to the tether.

In contrast to the piano-wire kite tethers used in the early measurements, present-day kite tether is normally Kevlar, Spectra, or some equivalent high-strength modern fiber. Typical tether diameters range from 1 to 3 mm. Proper tether selection is very important, since the weight of the tether can be a significant fraction of the payload weight. Also, tether drag increases significantly with the line diameter. Since the tether length is typically twice the height of the kite, both the tether weight and the drag are critical factors in achieving maximum kite heights. Typical tether breaking strengths lie in the range 100–400 kg.

For the kite sizes and line tensions outlined above, it is imperative to make use of some sort of winching system to raise and lower the kites under a wide variety of wind conditions. Typical requirements include the ability to allow the kite to be let out rapidly at low line tension and to bring it in reasonably rapidly under heavy wind conditions, i.e., at high line tension. An additional requirement is to be able to hold the kite on a fixed tether length for extended periods. It is also important to remember the inadvisability of winching the tether directly onto a take-up reel. One problem in using a direct take-up reel as a winch is that each additional wrap on the take-up reel under tension dramatically increases the inward force on the reel. Thus, the thousands of turns of Kevlar put directly onto a take-up reel at high tension will collapse the reel unless it is carefully designed. This problem was effectively demonstrated in 1899 at Blue Hill, when a \$10 000 heavy steel winch purchased for winding in a piano-wire kite tether was crushed beyond recognition when it was first put into operation.

In view of this problem, many meteorological kite systems incorporate a capstan to reduce the line tension prior to spooling the tether onto a take-up reel. A few turns around a capstan greatly reduces the line tension and thereby allows the line to be spooled easily onto a take-up reel. Capstans can be electrically driven or driven by gas or diesel engines. At remote field sites it is possible to use the rear wheel of a vehicle that has been replaced by a capstan, after blocking up the rear axle. In this operation, the vehicle's engine supplies the

necessary power, while the transmission enables the line to be reeled out or in rapidly. In addition, the line length can be fixed indefinitely by either the vehicle's brake or park system. As the tether comes off the capstan it can be wound at low tension around the take-up reel (a reel driven by a small gasoline engine or by a comparable electric motor using the car's battery as a power source). An artist's sketch of a vehicle-driven winch system lofting a parafoil kite (or a balloon) is shown in Figure 2.

Meteorological Payloads and Data Collection

Kite-borne payloads for meteorological measurements are limited by both weight and power requirements. A general rule of thumb is that the payload weight should not exceed 10 kg including its power source. (This is a practical and not a fundamental limitation. Man-lifting kites lifted payloads well in excess of 100 kg to high altitudes at the turn of the century.) In addition, the physical size of a payload must be reasonably small and/or aerodynamically shaped for minimal drag. Furthermore, the payload package must operate reliably within the temperature, pressure, and humidity constraints imposed by the environment. Other than that, a payload can consist of any type of instrumentation that meets the criteria outlined below.

Payload data collection can be accomplished by payload-to-ground telemetry, provided that such a capability is included in

Figure 2 Sketch of a winch system for kite/balloon-borne atmospheric studies that uses the rear wheel of a vehicle for motive power. Reproduced from Balsley, B., Jensen, M.L., Frehlich, R.G., 1998. The use of state-of-the-art kites for profiling the lower atmosphere. *Boundary Layer Meteorology* 87, 1–25.

the instrument payload. Alternatively, data can be stored onboard digitally for subsequent downloading after the payload has landed. The choice between these two possibilities involves consideration of the quantity of data being collected along with the possible need to control the payload position based on the on-line observations.

The standard meteorological measurements that have been made using kite-borne platforms since the turn of the twentieth century include vertical profiles of temperature, pressure, relative humidity, and wind. One example of the inherent vertical resolution of kite-borne wind speed and temperature profiles is shown in [Figure 3](#). In addition to these quantities, measurements that have been made over the past decades include both chemical properties (e.g., water vapor and ozone) and dynamic properties (e.g., atmospheric waves, instabilities, and turbulence properties). Future measurement possibilities are primarily limited by the payload limitations.

Payload Power Sources

The most obvious payload power source is batteries. Since most instruments can be designed to use low voltages (e.g., 5–18 VDC), it is possible to use batteries that are capable of maintaining the required voltage and current capabilities under relatively cold conditions (i.e., -20°C).

Alternative energy sources include both lightweight wind-powered generators carried aloft and solar cells. Wind-powered generators weighing roughly 1 kg can supply a few watts of power on a continuous basis. This technique can be useful, since a reasonably strong wind is all but certain if the kite is in the air. Moreover, since the wind blows night and day, only minimal power storage is necessary. Solar cells, on the other hand, are lighter in weight but require considerable storage for nighttime operations, since they supply power only under daylight conditions. Also, solar panels need to be oriented relative to the Sun's position.

A third possible energy source is the Earth's global electric field. Under clear-air conditions, vertical electric field magnitudes at typical kite heights are of the order of tens of volts per meter. Unfortunately, the source impedance of this 'supply' is quite high and extraction of reasonable amounts of power is problematic. Also, although the global electric field is predictable under clear-weather conditions, the presence of local convective activity produces greatly enhanced, and typically reversed, electric fields. Little work has been done to date to develop the Earth's electric field as a power source for kite-borne studies, although early attempts to extract power from the electric charges carried down a kite wire succeeded in driving a very small electric motor.

The WindTRAM

A recent innovation by a team at the University of Colorado, the WindTRAM (Tethered Rover for Atmospheric Measurements) has added an interesting new dimension to kite-borne atmospheric measurements. This development uses the kite as a 'sky hook', i.e., as a relatively stable, semi-fixed point high above the Earth's surface. With the kite at altitude, measurements can be made using instruments suspended below the WindTRAM. As shown in [Figure 2](#), the TRAM itself is basically a wing-like device that uses wind power to travel up and down the tether. The TRAM wing has an inverted airfoil to provide negative lift when the TRAM is traveling downward (away from the kite). Travel direction is controlled using conventional radio-control (RC) systems. Typical speeds along the tether are $3\text{--}9\text{ m s}^{-1}$, corresponding to vertical velocities of $2\text{--}6\text{ m s}^{-1}$. One advantage of the WindTRAM is that continuous raising and lowering of the kite to obtain profiles is obviated, so that profiles can be made more rapidly. One disadvantage of the technique is that wind speeds need to be greater than 5 m s^{-1} at all heights between the ground and the kite. This requirement is typically not met during nighttime conditions, when winds aloft are reasonable but the ground winds are either weak or nonexistent.

Figure 3 Measurements obtained using kite-borne sensors. This figure shows vertical profiles of wind speed and temperature measured from a sensor suspended below a kite over Kansas, USA at 02:13 LT on 18 October 1999 (ascent).

Advantages and Disadvantages of Data Gathering Using the Kite Technique

One major advantage of using kites for meteorological measurements is that they are relatively simple, lightweight, portable, devices that can operate in winds ranging from roughly 5 up to about 20 m s^{-1} . They are also capable of carrying reasonably sized payloads to altitudes of at least a few kilometers, and can remain aloft for days under ideal conditions. Moreover, the payloads are reusable, in contrast to those carried aloft by untethered balloonsondes that are normally not recovered. Kites can be flown either from land-based locations or from boats, with boat flights being somewhat preferable (except for the more confined working conditions), since the boat's velocity controls the effective wind seen by the kite. This last capability opens possibilities of inexpensive lower-atmospheric data collection at mid-ocean locations.

The primary restriction on the type (or types) of data collection lies with payload weight limitations. Multiple sensors can easily be carried aloft by the same platform. Also, many similar sensors can be attached at preset distances along a secondary line suspended from the main tether. This technique provides a more nearly vertical profile of the measured quantity. During ascent/descent periods, multiple sensors also provide a short-time history of such quantities as the sensors pass sequentially through the same regions. Alternatively, a pulley system on a secondary line can carry sensors from the ground to kite heights for more extended vertical profiles. Data gathered by meteorological kite systems can provide excellent height and time resolution profiles from the ground up to at least a few kilometers on a relatively continuous basis. Alternatively, measurements can, if required, be made for extended periods at a given altitude over a single location. Finally, atmospheric sampling is 'clean', in that the payload can be suspended well below the kite to minimize contamination and to minimize undesired 'blocking' effects that can occur in other types of atmospheric sampling.

There are a number of disadvantages to using kites for atmospheric sampling. One fundamental disadvantage is that kites require winds of at least $5\text{--}7 \text{ m s}^{-1}$ at kite level to remain aloft. Furthermore, kites are not all-weather systems and cannot fly during periods of high convective activity or in strong storm conditions. More importantly, perhaps, the principal difficulty encountered in many campaigns involves obtaining permission from the FAA (or its foreign equivalent for non-US flights) to fly the meteorological kite with payload higher than the normally allowed few hundred meters above the ground. Kites flying somewhat above these heights are of reasonable concern for small aircraft flying in the area. For greater heights, the problem extends to regularly scheduled commercial aircraft. This problem can normally be circumvented by obtaining a NOTAM (NOTice to AirMen) that prevents aircraft from temporarily flying in the area, or by flying in restricted areas in which aircraft are permanently prohibited from flying.

Synopsis

The radiosonde is a balloon-borne device that measures the vertical profile of meteorological variables (called a sounding) and transmits the data to a ground-based receiving and processing station. In 2012, there were 92 operational or synoptic radiosonde stations in the United States, which made a daily average of over 200 soundings; and there were over 800 radiosonde stations worldwide, which made a daily average of more than 1300 soundings. There are two primary purposes of upper-air soundings: to analyze and describe current weather patterns, and to provide inputs to short- and medium-range computer-based numerical weather prediction models. One very important, specialized use of atmospheric soundings is in support of forecasting hurricane movement and intensity. Special radiosondes called dropwindsondes are launched from weather reconnaissance aircraft to observe atmospheric structure within the hurricane as well as in the downwind area. Other uses of radiosonde data include scientific research, climate studies, air pollution investigations, aviation operations, and defense applications.

Introduction

The radiosonde is a balloon-borne device that measures the vertical profile of meteorological variables and transmits the data to a ground-based receiving and processing station. These profiles are typically obtained twice everyday and are the core of the ground-based weather observing system that provides inputs to numerical forecast models. The expendable sensor package routinely measures the variation with altitude of temperature, humidity, and pressure as the balloon ascends from the land or ocean surface to heights up to about 30 km (a pressure altitude of about 11 hPa). When the device also measures winds, it is more properly called a rawinsonde, although the term radiosonde is commonly applied to both. The height profile of these meteorological variables constitutes an upper-air sounding that is known as a radiosonde observation (RAOB). In some cases, a balloon without a radiosonde is tracked by either optical or radar techniques in order to measure only winds. This type of balloon is known as a pilot balloon or simply a pibal, but it is not a radiosonde.

In 2012, there were 92 operational or synoptic radiosonde stations in the United States, which made a daily average of over 200 soundings; whereas there were over 800 radiosonde stations worldwide ([Figure 1](#)), which made an average of over 1300 soundings everyday in support of weather forecast activities. Additional soundings are made for specialized purposes of which defense applications are the most significant. The global numbers of RAOB and pibal soundings are down considerably from their peak daily values in 1988 of 1660 and 964, respectively. The approximately half a million radiosondes used annually are manufactured by about 15 companies worldwide. Of these, the Vaisala company, headquartered in Helsinki, Finland, is the largest manufacturer. Vaisala was founded in 1936 by Professor Vilho Vaisala, who in 1931 invented one of the world's first radiosondes (see [Appendix](#)).

Since 1957 all stations make their soundings at the same times, 00.00 and 12.00 UTC, although many stations outside the United States and Europe have reduced soundings to one per day because of budgetary constraints. Countries launching operational radiosondes are members of the World

Figure 1 Global radiosonde station network.

Meteorological Organization's (WMO) World Weather Watch program; as such, they freely share their sounding data with each other. Shortly after an operational upper-air sounding is completed, a standard data message is prepared and made available to all nations using the Global Telecommunications System (GTS). Earlier the standard method was the so-called TEMP message (WMO standard format for upper-level pressure, temperature, humidity, and wind report from a fixed land station) reporting meteorological conditions at various standard or so-called mandatory (pressure) levels as well as at significant levels, which represent levels where prescribed changes in meteorological conditions occur. Currently, TEMP messages are being replaced by binary universal form for the representation of meteorological data (BUFR) code, which contains more detailed information of the sounding, as well as associated metadata.

There are two primary purposes of upper-air soundings: to analyze and describe current weather patterns, and to provide inputs to short- and medium-range computer-based weather forecast models. One very important, specialized use of atmospheric soundings is in support of forecasting hurricane movement. Special radiosondes called dropwindsondes are launched from weather reconnaissance aircraft to observe atmospheric structure in the core of the hurricane as well as in the area downwind of the storm itself (i.e., in the direction of the steering winds). These dropwindsonde measurements were the single most important factor in a 16–30% decrease in hurricane track forecast errors over the period 1982–93 (Burpee et al., 1996). And during 1997, the then-new GPS dropsondes reduced hurricane track forecast errors up to 32% and intensity forecast errors up to 20% in the five tropical cyclones that were studied (Aberson and Franklin, 1999). More recently, Weissmann et al. (2011) report typhoon track forecast improvements using the NCEP and WRF models of 20–40% during the 2008 THORPEX Pacific Asian Regional Campaign, but smaller improvements associated with the ECMWF and JMA model track forecasts. Other uses of radiosonde data include climate studies, air pollution investigations, research, aviation operations, and defense applications. The radiosonde continues to be the backbone of an eclectic suite of measurement technologies (measurements both remote and *in situ* that are made from ground-based, airborne, and satellite platforms) used to provide data for input to numerical weather prediction models.

Radiosonde Operations

The radiosonde is carried aloft by a balloon as part of a flight train (Figure 2). The balloon itself may be made of either natural rubber (latex) or synthetic rubber (neoprene). The mass of the flight train, the desired ascent rate, the type of gas used, and the maximum height of the sounding determine the size of the balloon. Operational radiosonde systems typically use balloons that weigh anywhere from 300 to 1200 g; they are filled to ensure an ascent rate of 300 m min^{-1} (5 m s^{-1}). Hydrogen is the most commonly used gas to inflate the balloon, due to its lifting capacity, although helium and natural gas are sometimes used for special applications. The flight train consists of five components: (1) the balloon; (2)

Figure 2 Typical radiosonde flight train, including balloon, parachute, unwinder mechanism, separation line, and radiosonde. © Vaisala company. Reproduced with permission.

a parachute to bring the radiosonde safely back to Earth after the balloon bursts; (3) 20–60 m of nylon separation line that isolates the radiosonde's sensors from potential water vapor and thermal contamination by the balloon; (4) a de-reeler to let out the nylon line after launch; and (5) the radiosonde itself. A few countries such as the United States and Switzerland actively seek to recover and then reuse their radiosondes. In the United States, it is estimated that 10–15% are reused after extensive refurbishment, while in Switzerland, more than 60% are recovered and reused.

In addition to the radiosonde, the sounding system includes ground equipment to receive, process, and forward the meteorological information. The ground equipment receives the data signals from the radiosonde, performs data filtering and quality control, and then produces the output data sets in the form of messages, graphics, or data listings. Typically, the system consists of a sounding processor unit, receiving antenna, radiosonde ground check unit, and a computer (see Figure 3).

Components of the Modern Radiosonde

The radiosonde is an electronics unit that comprises three major sections: a suite of sophisticated meteorological sensors, signal-processing electronics, and a radio transmitter to relay the measurements back to a receiver at the radiosonde launch station. The meteorological measurements are made at intervals

Figure 3 Components of a radiosonde sounding system. 1. Sounding workstation; 2. sounding processing subsystem; 3. ground check set; 4. radiosonde; 5. GPS antenna; 6. UHF antenna. © Vaisala company, Helsinki, Finland. Reproduced with permission.

that vary from 1 to 6 s, depending on the type and manufacturer of the radiosonde. The meteorological community has been assigned two radio frequency bands for use in transmitting meteorological data: 400.15–406 MHz and 1668.4–1700 MHz. These bands are under continuing pressure from the telecommunications industry, which seeks to use them for commercial, nonmeteorological purposes. All of the world's radiosondes are required to meet certain performance standards that have been established by the WMO (see Table 1). Figure 4 illustrates four different radiosondes currently in use around the world.

Overview of Thermodynamic Sensors

Thermodynamic sensor types vary widely among radiosondes currently in use throughout the world. Temperature sensors are of four designs: capacitance sensors, thermistors, metallic resistive sensors, and thermocouples. The two common humidity

elements are carbon hygriators and planar thin-film capacitance sensors. Pressure measurements are typically made with either an aneroid cell or a micromechanical silicon pressure sensor. Also, in some recent designs the pressure sensor is replaced with pressure reading calculated from GPS-derived height, temperature, and humidity, using the hydrostatic equation. There are about a dozen different radiosonde designs presently in use. As radiosondes have become more advanced, their changes have also created special challenges to climatologists seeking to piece together a consistent and homogeneous, multidecadal global database to analyze and understand climate change. As a result, climate researchers must account for biases in the historical records due to changes in instrumentation and observing methods, many of which have poor or no documentation. In the United States alone, these changes have been varied and significant. Four distinctly different humidity sensors have been in use since 1943. Temperature measurements have undergone major changes, including sensor type, size, coating, exposure to the air

Table 1 Accuracy requirements (expressed as standard error) for upper-air measurements for synoptic meteorology

Variable	Range	Accuracy requirement
Pressure	Surface to 5 hPa	± 1 hPa
Temperature	Surface to 100 hPa	± 0.5 K
	100–5 hPa	± 1 K
Relative humidity	Troposphere	$\pm 5\%$ (RH)
Wind direction	Surface to 100 hPa	$\pm 5^\circ$ for wind speed $< 15 \text{ m s}^{-1}$
		$\pm 2.5^\circ$ for wind speed $> 15 \text{ m s}^{-1}$
Wind speed	100–5 hPa	$\pm 5^\circ$
	Surface to 100 hPa	$\pm 1 \text{ m s}^{-1}$
	100–5 hPa	$\pm 2 \text{ m s}^{-1}$
Geopotential height of significant levels	Surface to 100 hPa	$\pm 1\%$ near the surface decreasing to $\pm 0.5\%$ at 100 hPa

stream, and corrections to account for radiation biases. At present, the US National Weather Service uses radiosondes from two different manufacturers, each having its own distinct set of pressure, temperature, and humidity sensors.

In that the Vaisala company is the largest manufacturer of the world's radiosondes, added emphasis is given below to aspects of the design of its radiosondes and sensors.

Thermodynamic Sensors: Pressure, Temperature, and Humidity

Traditionally, all sensors used with Vaisala radiosondes have been of the capacitance type. This, however, changed in 2013 with the introduction of Vaisala RS41, which has a resistive temperature sensor. In capacitive sensors, changes in pressure, temperature, and humidity result in changes in the capacitance information from each sensor, which in turn is changed to a frequency signal by using sensor transducer electronics. Sensor frequency measurements are compared with the frequencies of reference capacitance transducers, and these in turn are converted to physical measurements based on factory calibration measurements.

In the case of pressure, the distance between capacitance plates changes as atmospheric pressure changes, causing a change in the measured capacitance. Older pressure sensors used an aneroid or bellows-type sensor that responds

mechanically to pressure changes. Modern pressure transducers are very small silicon, micromechanical pressure sensors. Pressure sensors also have a temperature dependence that is compensated by factory calibration of the sensor. Modern GPS technology has also made possible a design, where the pressure sensor is replaced with GPS-derived pressure reading, calculated from GPS height, temperature, and humidity using the hydrostatic equation. Vaisala RS41-SG is the first radiosonde model utilizing this technology.

In capacitive temperature sensors, temperature is measured by the change in the dielectric constant of the sensor. In the latest Vaisala model, RS41, the capacitive temperature sensor is replaced with a resistive platinum sensor, specially designed for stability and robustness. Essential aspects of modern temperature and humidity sensors (and their supporting members such as the sensor boom; see Figure 5) are their different coatings and treatments to minimize solar heating and improve water repellency.

The approach used to measure humidity in all Vaisala radiosondes is also based on changes in the dielectric constant. The humidity sensor is manufactured using thin-film technology. The dielectric material is a very thin layer of a special proprietary polymer that has an optimum combination of measurement properties, including stability, repeatability, hysteresis, response time, and temperature dependence. Thin-film humidity sensors are calibrated to provide output in terms of percent relative humidity with respect to water; the

Figure 5 Vaisala RS41 radiosonde with sensor boom. © Vaisala company, Helsinki, Finland. Reproduced with permission.

temperature dependence is compensated by use of temperature-dependent calibration coefficients determined from factory calibration tests.

The accuracy of radiosonde data is a combination of multiple factors: sensor performance, related transducer electronics, mechanical construction of the sonde and sensor housing, sensor and sensor-boom coatings and treatments, calibration technology, and calibration and correction algorithms. In addition to issues of radiosonde performance, the uncertainty of upper-air measurements includes sampling considerations, such as the density of the observation network, time interval between observations, and the homogeneity of the atmosphere. Together, these instrumental and environmental factors govern the accuracy and representivity of the observations.

Specialized Radiosonde Sensors

Some radiosonde manufacturers offer optional sensors to make supplemental environmental measurements. Additional electronics are used to interface the supplemental sensors to the radiosonde. Ozone concentration is the most common supplemental measurement. Radiosonde measurements of ozone are made worldwide, although at fewer stations and typically only once in a day or less often. The most common radiosonde ozone sensor is the electrochemical type. Other supplemental measurements in use today include dew point, optical backscattering by fine particles, electric field, and video imaging of particles and hydrometeors. Most advanced radiosonde ground systems effectively support both synoptic and research users, and offer options for post-ascent data calculation and analysis of supplemental measurements.

The Vaisala ozonesonde consists of an electrochemical ozone sensor connected to an interface unit and a radiosonde. Consequently, humidity, pressure, temperature, and geopotential height can be measured simultaneously with ozone sampling. Upper-air winds are also measured. This lightweight, balloon-borne instrument is capable of measuring the vertical distribution of atmospheric ozone up to a pressure altitude of 3 hPa. The uncertainty of the ozone measurement is of order 5–10% of the local value. The electrochemical concentration cell (ECC) detects ozone on the basis of an iodine–iodide oxidation–reduction or redox electrode reaction in a neutral-buffered solution. The sensor consists of an ECC that contains two platinum electrodes immersed in separate potassium iodide solutions of different concentrations that are separate anode and cathode chambers. The chambers are linked with an ion bridge. As the air containing ozone flows into the cathode solution, a chemical reaction occurs and the platinum electrodes carry electrons between the cells of the sensor. An electrical current is generated in proportion to the rate at which ozone enters the cell. The ozone concentration is determined from the electric current measurement using an equation that considers the airflow rate, air pressure, and pump temperature. The interface can also be used with other sensor types, such as the Brewer–Mast sensor. However, the Brewer–Mast sensor is nowadays almost totally replaced with the widely used ECC-type sensor, which is also more accurate.

Overview of Windfinding

There are several techniques for measuring winds only with a balloon or with a combination of balloon and radiosonde. When a radiosonde measures winds it is called a radio wind sonde or rawinsonde, and the windfinding methods vary widely. In all cases, the winds are determined by measuring the drift of the balloon. One class of wind measurement techniques tracks the balloon externally using one of the three methods: (1) optical systems use a theodolite to visually track the balloon's azimuth and elevation; (2) radio theodolites track a radio signal sent from a transmitter on the radiosonde, again to obtain azimuth and elevation information; and (3) radar systems track a radar retroreflector suspended from the balloon to obtain slant range, azimuth, and elevation. The second class of wind measurement techniques uses various navigation systems. Earlier the LORAN-C navigation system and various very low frequency (VLF) systems, such as the Russian ALPHA system and the US Navy's VLF system were commonly used. Currently, Global Positioning System (GPS) technology has replaced these older navigation systems; a GPS receiver directly measures the drift velocity of the balloon and hence the wind. Two major advantages of the GPS-based techniques are the high accuracy and precision of the wind measurements, and the worldwide coverage of GPS.

Tracking Techniques

Optical Tracking Methods

One of the earliest methods for determining the winds aloft was to visually or optically track small balloons, called pibals.

This method was developed in the mid-1870s using a small expendable balloon tracked with a small telescope. The small optical device, similar to a surveyor's transit, is called a theodolite and can accurately measure elevation and azimuth angles. If the balloon's height can be determined then its position can be found by trigonometry. There are basically two pilot balloon techniques still in use: (1) single-theodolite and (2) double-theodolite techniques. In the former, the elevation and azimuth angles of the balloon are measured at regular intervals (typically once in a minute). Balloon altitude is determined by assuming a constant ascent rate that is determined from the size and free lift of the balloon. Balloon position is then calculated from the height and the azimuth and elevation measurements. Tracking the balloon during a nighttime observation is accomplished by attaching a light stick or a small battery-powered light. In the double-theodolite technique, two theodolites are located at a known distance apart (the baseline) and simultaneous observations taken of the balloon at given time intervals. By measuring the azimuth and elevation angles of the balloon from the two known positions, the three-dimensional balloon position can be determined by the law of sines. The double-theodolite method enables accurate measurements of the balloon position without assuming a constant rate of ascent for the balloon, which can be a source of error. In this method, the baseline distance needs to be accurately measured and should be at least one-fifth of the maximum range to the balloon. The baseline should also be perpendicular to the prevailing winds. The method is not routinely used because of baseline restrictions and the cost and difficulty of coordinating two sets of observers.

Radio Theodolite, Radar, and GPS Methods

Another tracking technique used for determining winds is called radio direction finding (RDF). During World War II, the US Army Signal Corps developed the first RDF system, called the SCR-658. This system operated at 400 MHz and used two separate operators to steer a large antenna array to determine the direction of the radiosonde transmitter. A more modern RDF antenna automatically tracks the 1680 MHz telemetry signal transmitted from the radiosonde. The antenna azimuth and elevation data are sent to a computer at the ground station along with the pressure height data from the radiosonde to determine the change in radiosonde position (winds) during flight. The RDF technique (Figure 6) is the radio frequency equivalent of the optical theodolite method, and the tracking system is called a radio theodolite. There are different types of RDF antennas, including 2–3 m diameter dish antennas and phased array flat-plate antennas. RDF systems can resolve the azimuth and elevation angles to within 0.05° . If the upper level winds are high then the radiosonde will be a long distance away, resulting in the antenna elevation angle being near the horizon. At stations that experience high winds, the radiosondes can be equipped with a transponder to measure slant range or distance to the radiosonde. Winds can then be determined using azimuth, elevation, slant range, and height of the radiosonde. A similar method for tracking the radiosonde uses a radar reflector on the balloon flight train so that it can be tracked by

Figure 6 Angle-dependent tracking system.

windfinding radar. Slant range to the radiosonde is measured by the radar as well as azimuth and elevation angles. Radar windfinding is a common method used in many countries around the world; in 1998 about 45% of the stations used radar, as tallied in Oakley (1998).

In some countries, a combination RDF-transponder method is used, called secondary radar. The parabolic or array-type RDF antenna transmits a short pulse that is received by the radiosonde. The radiosonde then 'wakes up' and retransmits the pulse, encoding the temperature and humidity data, which are received by the ground-based RDF antenna. The RDF antenna azimuth and elevation angles are measured and the slant range is determined from the travel time of the pulse. Secondary radar systems use radiosondes that do not have a pressure sensor as pressure is calculated from the hydrostatic equation.

GPS Windfinding

LORAN or Omega NAVAID usage for radiosonde windfinding is no longer being used or supported and has been replaced by GPS. GPS was conceived in the early 1970s for the US Department of Defense, and is operated by the US Air Force. The GPS system became fully operational in late 1995. There are 24 satellites in six-orbital planes spaced 60° apart. The satellites are in a 200 km circular orbit, with an inclination angle of 55° and a periodicity of 12 h. At any time or place in the world, there are 6–11 GPS satellites 5° or more above the horizon and hence usable for GPS windfinding. There are two primary GPS techniques for determining winds from radiosondes. The GPS signals cannot be retransmitted from the radiosonde back to the ground because the bandwidth of the 1575 MHz (called the L1 band) GPS carrier signal is too wide (B2.0 MHz). The worldwide civilian use of GPS has become so great that many manufacturers produce inexpensive small GPS receivers, each the size of a credit card that can decode the navigation message every second and produce accurate

Figure 7 USAF C-130 Hurricane Hunter launching a GPS dropsonde.

three-dimensional position coordinates as well as speed and heading. A second, less expensive method uses a codeless receiver in the radiosonde that measures only the Doppler shift of the carrier frequency. The Doppler shift has two components: (1) the Doppler shift due to the satellite motion (i.e., the largest component) and (2) the Doppler shift due to radiosonde movement. The radiosonde receiver sends the Doppler information back to the ground data system. The ground data system must have a local GPS receiver that can decode the GPS message and independently measure the Doppler shift from each satellite. The satellite Doppler shift is subtracted from the radiosonde Doppler shift and the difference yields the radiosonde motion.

Specialized Types of Radiosonde Systems

Dropsonde

The dropsonde is the airborne counterpart to the conventional radiosonde (sometimes also called an upsonde). Dropsondes are ejected from research and reconnaissance aircraft and float to earth on a special balloonlike parachute. Current state-of-the-art dropsonde sensors include capacitance fine-wire sensors to measure temperature, capacitance silicon pressure sensors, and GPS receivers to measure winds. Humidity is measured with a pair of thin-film capacitance sensors that are heated alternately to avoid condensation on descent from colder to warmer air. All measurements are made twice every second, while the 400 g dropsonde falls at an initial rate of about 25 m s^{-1} at 15 km altitude, decreasing to about 10 m s^{-1} at sea level. Dropsonde data are transmitted by radio from the sonde to a data system in the aircraft. Atmospheric soundings from dropsondes provide the ability to measure conditions over remote areas such as the oceans, polar regions, and sparsely inhabited landmasses; they also provide a means to obtain soundings in and around severe weather systems, such as

hurricanes. Atmospheric soundings obtained from dropsondes during hurricane reconnaissance flights have improved the accuracy of forecasts of hurricane landfall by about 20% over the decade of the 1990s. Dropsondes were first developed in the 1960s for the US Navy and Air

Figure 8 GPS dropsonde descending on its parachute.

Force for hurricane reconnaissance and were an adaptation of radiosonde technology. These early dropsondes were heavy – about 2.5 kg – and did not have inherent wind-finding capability; windfinding at that time still used only radar or RDF. With the development of Omega NAVAJD windfinding technique for the radiosonde, it became possible to incorporate that technology into the dropsonde. This occurred in 1974 when the National Center for Atmospheric Research (NCAR) developed an Omega Dropwindsonde (ODW) for use in the Global Atmospheric Research Program's Atlantic Tropical Experiment. In 1982, the Air Force adopted the ODW system for hurricane reconnaissance and this system was used until the early 1990s. In 1985, NCAR began development of a smart (i.e., microprocessor-based), lightweight digital dropsonde that

incorporated LORAN and Omega windfinding. The Omega version of this dropwindsonde was adopted by the US Air Force in the early 1990s for its hurricane reconnaissance mission (Figure 7). The next major improvement in dropsonde technology occurred in 1995 when NCAR completed development and testing of a new GPS dropsonde with codeless GPS windfinding capability and an advanced aircraft data system (AVAPS). In 1996, NCAR licensed Vaisala Company of Woburn, Massachusetts, to commercialize production and sales of the GPS dropsonde (Figure 8) and AVAPS. In the relatively short time, the GPS dropsonde has been in use it has found research applications in the determination of hurricane structure and motion, the study of clear-air turbulence associated with upper level jet stream structure, and observing strategies for midlatitude weather

Figure 9 Remote-controlled GPS dropsonde launcher system installed on the NASA ER-2 high-altitude weather research aircraft.

Figure 10 The driftsonde system concept.

forecasting. Current adaptations of the GPS dropsonde technology are focusing on launches at higher altitudes – including the lower stratosphere – as well as autonomous launches that eliminate the need for operators to launch the sonde and record the data, and offer the promise that it will be possible one day to obtain operational dropwindsonde profiles from commercial aircraft. [Figure 9](#) shows a test dropsonde launcher mounted on the underside of an ER-2 high-altitude weather research aircraft.

Driftsonde System

Improvements in short- and medium-range synoptic-scale weather forecasts will depend on improved upper-air soundings over the data-sparse regions of the Northern and the Southern Hemispheres. Progress toward this objective will require the optimal use of existing data sources, creative new observing methods, and improved numerical methods for data assimilation. The driftsonde system is being developed as a cost-effective sounding system that could fill these critical gaps in data coverage over oceanic and remote arctic and continental regions. The driftsonde concept seeks to obtain a large number of high-vertical-resolution GPS dropsonde profiles through the lower stratosphere and the entire troposphere by autonomous launching of dropsondes from specially designed balloon platforms. The driftsonde system includes a polyethylene carrier balloon with an attached gondola ([Figure 10](#)) that carries a payload of up to 24 GPS dropsondes. The carrier balloon ascends to between 50 and 100 hPa (20 and 16 km), and then drifts in the prevailing stratospheric winds for up to 5 days, deploying dropsondes at prescribed and special times over data-sparse regions of interest. The first application of the driftsonde system was in support of The Hemispheric Observing System Research and Predictability Experiment (THORPEX). The driftsonde system has been deployed in three field experiments associated with THORPEX (Cohn et al., 2013): AMMA (African Monsoon Multidisciplinary Analyses, 2006), T-PARC (THORPEX Pacific Asian Regional Campaign, 2008), and Concordiasi field experiment (lower stratosphere and troposphere study above Antarctica, 2010).

Unmanned Sounding Systems

Autosonde

A special type of ground equipment is the unmanned, automated sounding system (Autosonde); see [Figure 11](#). It was first introduced by the Vaisala company in 1992. These automatic sounding systems have become an important tool in the drive for meteorological data availability. Using them, weather services can extend the coverage of their upper-air networks to geographically remote, hard-to-reach locations and decrease sounding costs. A typical Autosonde system has the capacity to perform automatically for 24 consecutive soundings, meaning that in synoptic use (2 soundings per day) it needs to be visited and restocked only with interval of 12 days. There are currently about 60 unmanned Vaisala sounding systems in operation globally.

Figure 11 Equipped with special cold climate kit, the Autosonde systems can be used in temperatures below -40°C . © Vaisala company, Helsinki, Finland. Reproduced with permission.

Automated Shipboard Aerological Program

Gathering synoptic weather observations over the oceans is an important complement to land-based meteorological upper-air observations. The Automated Shipboard Aerological Program (ASAP) is a multinational effort initiated by Canada in 1982 to obtain upper-air soundings over the oceans. Radiosondes are launched from commercial ships of opportunity using a specially designed launch system ([Figure 12](#)) that permits flight trains to be launched in high-wind conditions. The upper-air sounding data from the radiosonde are sent back to the shipboard ASAP system where the data are processed in near real time to create a TEMP SHIP message (the WMO standard format for upper-level pressure, temperature, humidity, and wind report from a sea station). This message is the ocean equivalent of the TEMP message generated for land-based RAOB systems. The ASAP system sends the message to a geostationary satellite that relays the information to the GTS, which then transmits it to the numerical weather prediction

Figure 12 The ASAP system is housed in either a standard 3 or 6 m (shown above) sea container with a specially designed hatch to enable routine radiosonde launches in sustained wind up to 25 m s^{-1} (gusts up to 35 m s^{-1}).

centers around the world. The ASAP program had its beginning in June 1981, when Canada decided to discontinue its weather ship program owing to the high costs of operating and maintaining the ocean weather ship PAPA located in the Gulf of Alaska at 50° N , 145° W . The original intent was to replace the weather ship data with satellite observations; however, persistent cloudiness in areas such as the Gulf of Alaska and the North Atlantic coupled with the lack of surface weather data, made this goal impossible to attain. To remedy this problem, the Atmospheric Environment Service (AES) of Environment Canada, the National Weather Service of National Oceanic and Atmospheric Administration (NOAA), and National Center for Atmospheric Research (NCAR) established a joint ASAP project to develop a modular, mobile, moderately priced, upper-air sounding system. This system, when placed on commercial vessels (ships-of-opportunity) routinely crossing the Pacific Ocean and the Atlantic Ocean, provides real-time upper-air soundings that complement those of the global land-based upper-air network. The ASAP program operated by AES Canada started in the spring of 1982 with one commercial ship (a Japanese automobile carrier) that operated from Vancouver, British Columbia, to Japan. By 2012, it had evolved into an international program coordinated by EUMETNET, operating 19 ASAP units and delivering 4700 radio soundings per year.

Reference Radiosondes

In 2007, the WMO's Global Climate Observing System (GCOS) laid out the need for a GCOS Global Reference Upper-Air Network (GRUAN). They concluded (Seidel et al.,

2009) that shortcomings in the current upper-air measurement network do not satisfy the accuracy and detail of observations needed to specify climate variability and changes above the Earth's surface. This deficit greatly impacts the ability to accurately assess and predict climate change. The overall goal of GRUAN is to establish about 30 stations that will use reference grade radiosondes in addition to other instrumentation to represent climate around the world. Currently (2013), the network consists of 15 initial GRUAN stations around the globe. The network construction and operations are coordinated by the GRUAN Lead Centre at the Meteorological Observatory Lindenberg (Germany), run by the German National Meteorological Service, the Deutscher Wetterdienst.

Climate variables to be observed with the highest priority are temperature, water vapor, and pressure. The vertical range for these observations is between the surface and the middle to upper stratosphere. Currently, the largest challenge is the observation of water vapor in the upper troposphere and lower stratosphere, and considerable development in sensing technologies will be needed to expand the current capabilities to observe this climate variable using *in situ* sounding instrumentation. One of the ongoing efforts in this direction is the Reference Radiosonde Program launched by Vaisala company in 2009. To fulfill the accuracy requirements, the Vaisala Reference Radiosonde RR01 will use an extremely sensitive, new type of capacitive dew point sensor to complement the standard radiosonde sensors. Currently (2013), Vaisala RR01 has entered the beta testing phase.

Appendix

Historical milestones leading to the development of the modern meteorological radiosonde

<i>Year</i>	<i>Milestone</i>
1643	Evangelista Torricelli invents the barometer in Florence, Italy.
1648	French mathematician Blaise Pascal observes the decrease of atmospheric pressure with altitude.
1749	Alexander Wilson, Glasgow, Scotland, uses kites to study the variation of temperature with altitude.
1783	The French Montgolfier brothers Joseph-Michel and Jacques-Étienne invent the hot-air balloon.
1783	Jacques Alexandre Césaire Charles, Paris, France, uses a manned balloon to make the first measurements of variations of pressure and temperature with altitude.
1784	Englishman John Jeffries, London, and Frenchman Jean-Pierre Blanchard begin the systematic study of the atmosphere using manned balloons.
1804	French physicists Louis Gay-Lussac and Jean Baptiste Biot ascend to 7 km in a balloon and discover that water vapor decreases with altitude.
1822	Englishmen Sir Edward Parry and the Rev. George Fisher use kites with recording thermometers to study the Arctic atmosphere.
1847	William Radcliff Birt is the first to measure winds aloft (and temperature) with a kite flown from Kew Observatory, London.
1892	Frenchmen H. Hermite and G. Besançon launch the first free-flying weather balloon with mechanical recording system (the 'meteorograph').
1893	Lawrence Hargrave, Sydney, Australia, invents the box kite; by end of the decade, many major observatories are using box kites routinely to measure the atmosphere; they include Blue Hill (near Boston, Massachusetts), the Central Physical Observatory (Moscow), Trappes (near Paris), Kew (London), Lindenberg (Germany), and Ilmala (Helsinki).
1900	British scientist W.H. Dines invents the mechanical meteorograph design that is widely used until 1939.
1901	Richard Assmann, Germany, is first to use 'extensible' rubber balloons for free-flying soundings with meteorographs.
1917	Germans F. Herath and M. Robizsch use the 'telemeteorograph' to transmit meteorological data from a kite using the steel kite cable as the signal cable.
1920	US Weather Bureau and Army Air Corps establish a program of daily upper-air soundings using airplanes at 20 locations nationwide.
1921	US Weather Bureau establishes a kite network for routine upper-air observations; this remains in operation until 1933.

<i>Year</i>	<i>Milestone</i>
1927	M.R. Bureau and M. Idrac (France) invent the 'shortwave' (RF) tube-type transmitter and publish a paper describing the flight of their first balloon-borne sonde (although it is unclear whether any meteorological variables were actually measured). Their paper is the first documented use of the term 'radiosonde,' which they attribute to H. Hergesell (president of the international aerological commission).
1929	January 17: M. Idrac and M.R. Bureau test the first free-flying radiosonde, called the 'Thermoradio,' with a bimetallic temperature sensing element to transmit temperature data to a ground station.
1930	January 30: P.A. Moltchanov (Russia) uses a radiosonde to measure temperature and pressure to a height of 10 000 m from Slutsk. From 1930 to 1936, several thousand soundings were made in the USSR with the Moltchanov radiosonde. May 8: M.R. Bureau launches a radiosonde measuring temperature and pressure from Trappes, France, reaching an altitude of 14 400 m. May 22: P. Duckert (Germany) flies the first radiosonde measuring pressure, temperature, and humidity to a height of 15 000 m from the Aerological Observatory at Lindenberg.
1931	December 30: Prof. Vilho Väisälä (Finland) flies a radiosonde from Helsinki telemetering temperature to the ground up to a height of 7 km; like Duckert, Väisälä used the measuring elements to control the capacitance of the radio oscillator circuit.
1936	July 30: Prof. Väisälä establishes the Vaisala company and delivers the first commercial order for 20 radiosondes, delivered to Prof. Carl Gustav Rossby at the Massachusetts Institute of Technology.
1974	The National Center for Atmospheric Research (Boulder, Colorado) develops the dropsonde, a special radiosonde that is launched from research aircraft and measures winds, pressure, temperature, and humidity while descending on a parachute.
1976	The Vaisala company (Helsinki) introduces the first computer-controlled upper-air sounding systems.
1982	The US National Oceanographic and Atmospheric Administration begins routine use of dropsondes for hurricane research; 1 year later, the US Air Force initiates its hurricane reconnaissance program.
1995	The first commercial radiosonde systems using the satellite Global Positioning System to measure winds are introduced by the Atmospheric Instrumentation Research company (Boulder, Colorado) and the Vaisala company (Helsinki).
2005	The GCOS Reference Upper-Air Network (GRUAN) development is launched.

Introduction

The influence of the lower atmosphere on our daily lives is immediately clear because of the weather processes that occur there. The processes that occur in the upper atmosphere are also important, although that did not become evident until the space age began at the end of World War II. As we become more dependent on space and satellite communications, as well as traditional radio communications, understanding those processes becomes critical. The ionosphere, which covers the region from approximately 80 km to altitudes above 1000 km, is a mixture of neutral gas constituents and charged particles. The plasma, as it is known, and the electrodynamic forces that drive it can produce small-scale fluctuations in the charged particle densities that can affect radio and satellite communications significantly. The temperatures, composition, and density of the neutral gas component can also have large variations in response to both local processes and changing activity on the Sun. Such effects can alter satellite and other spacecraft trajectories enough to be a concern. Measuring the properties of the atmosphere at high altitudes where the dynamical properties are both interesting and important but where the densities are low enough to make measurements difficult has been a continuing challenge, especially in the period since World War II. The measurement techniques used extensively include ground-based remote sensing with radars and optical techniques, measurements from satellites, and measurements from suborbital rockets, also known as sounding rockets. This article will focus on the techniques used to obtain measurements from the rocket platform.

The layers of the atmosphere closest to the surface of the Earth are the troposphere and stratosphere. Above 45 to 50 km altitude, where the stratosphere ends, the temperature again decreases with altitude in the layer known as the mesosphere, followed by a region of steadily increasing temperature above 90 km, known as the thermosphere, where the absorption of extreme ultraviolet radiation from the sun is primarily responsible for the temperature increase. Radiation from the Sun also leads to the ionization of neutral particles in that region which, because of the importance of the charged constituents, is also known as the ionosphere.

Between the surface of the Earth and the region near 100 km altitude, the density of the atmospheric gas decreases by a factor of approximately 1 000 000, and traditional techniques for making measurements *in situ* from platforms such as balloons or aircraft do not work, since the platforms cannot be supported by the atmosphere. New possibilities for probing the upper-altitude regions became available at the end of World War II when rockets developed by the Germans during the war and captured by the Allies became available for scientific investigation.

History

Sounding rocket studies of the upper atmosphere began in 1946 shortly after the conclusion of World War II. At the close of the war in Europe, the Allies captured the remaining German supply of V-2 rockets that were developed at Peenemunde and used in the bombing of Britain. The V-2 was 14 m in length, weighed almost 13 000 kg, and had a range of over 300 km. In all, 67 complete rockets were assembled at White Sands, New Mexico, from captured parts. 60 were ultimately launched between 1946 and 1952, and a number of these flights were used to make measurements in the upper atmosphere. In a vertical flight, the V-2 could reach an altitude exceeding 160 km, i.e., well into the ionosphere.

It was clear from the outset that the supply of V-2 rockets was limited, and development of rockets designed specifically to be sounding rockets started almost immediately. These included the WAC Corporal which was first developed before the war and the Aerobee. The new rockets had limited capabilities, however. The WAC Corporal, for example, was only able to reach an altitude of 70 km with a payload of 11 kg, and the Aerobee could reach 100 km with a 70 kg payload. By comparison, the V-2 could carry a 1000 kg payload to an altitude of 160 km. The Viking was the first sounding rocket that provided capabilities comparable to the V-2, with a maximum performance that allowed it to reach an apogee of 220 km with a payload weight of 340 kg. In all, 47 V-2 rockets, 91 Aerobees, 8 Vikings, and 1 V-2-boosted WAC Corporal were fired at White Sands in the upper-air program between the spring of 1946 and the fall of 1952. The newer designs during that period focused increasingly on the solid propellants that are still used today rather than the liquid fuels, such as the ethyl-alcohol-based fuel used in the V-2. Solid fuel made storage and handling much safer and simpler.

Launches from White Sands of various sounding rockets continued throughout the period up to 1956 at which time planning for what became known as the International Geophysical Year (IGY) began in earnest. Part of the emphasis of the IGY was to provide detailed global observations of the upper atmosphere using both ground-based and rocket measurements. A series of launches were carried out in the year leading up to 1958, with a large number of launches in the International Geophysical Year itself. By this time the importance of the near space region for communications, satellites, and weapons systems was clear, and the National Aeronautics and Space Administration (NASA) was established on 29 July 1958 as a central organization that would act as the focus for space research. At that time, much of the sounding rocket activity designed to provide critical measurements of upper-atmosphere parameters was moved to Wallops Station on the east coast of the Delmarva Peninsula in Virginia. Other NASA facilities also continued to support sounding rocket activity, as did the research labs within the military branches. Eventually all sounding rocket activity in the United States became

consolidated at the Wallops Flight Facility in 1980. Since the NASA sounding rocket program began in 1958, there have been over 2800 science flight missions.

The first sounding rocket program for studies of the upper atmosphere was developed and continues today in the United States, but a number of other countries have also had and continue to have extremely active rocket programs. Ongoing programs include those in Japan, India, Norway, Sweden, Canada, and Brazil, all of which have active permanent launch facilities. Other countries that have carried out launches at various times in the past include Germany, France, Italy, Spain, Denmark, Australia, and Pakistan. In addition to the fixed launch facilities, a number of remote sites have also been used on a campaign basis for special-purpose launches. These have included Peru, Greenland, Puerto Rico, and North Africa. The maximum launch rate in the United States occurred in the mid-1960s with over 190 launches in 1965. The program currently provides 20–30 flight opportunities per year with launches from a variety of launch sites throughout the world. The level of activity worldwide varies, although the trends are the same as in the United States, with a decrease in the number of launches today as compared with the 1970s, for example.

In part the launch rate has decreased because of the improvements and greater availability of ground-based remote sensing and satellite techniques and in part because the size and complexity of the rocket payloads has increased, so that the rockets being flown today are, in fact, sophisticated spacecraft that cost more and require a longer time to design, manufacture, and test. In the early days of the sounding rocket program immediately after World War II, the payload instrumentation was often quite simple, with a single sensor and a payload weight of a few kilograms. As the technology has advanced and the science questions have become more complicated, the payloads have also become larger and more complex. Sounding rockets today often carry suites of 5–10 different instruments, have attitude control systems to orient the payload in different directions during the flight, and in some cases even have independent sections with instruments and telemetry that separate from the main payload so that large-scale gradients or fluctuations in the medium can be measured.

The increase in mass and volume has led to the requirement for more powerful vehicles. Some vehicles are made specifically for scientific applications. Notable examples are the Black Brant rockets made by Bristol Aerospace in Canada and the Japanese S-series rockets. The United States uses a combination of science vehicles and military surplus rockets such as the Taurus, the Nike, and the Orion for the scientific sounding rocket experiments. Many of the rockets used today are two- or even three-stage vehicles, and payload diameters are generally 14–17 inches (36–44 cm). The Black Brant XI, for example, is a three-stage vehicle that can reach altitudes close to 600 km with a 300 kg payload. The vehicles used today for sounding rocket studies use solid fuel exclusively.

Safety requirements dictate that launches can take place only in isolated locations, since a sufficiently large area has to be available for the unguided rockets to impact safely without danger to people or property. This condition is satisfied in a few places where established ranges exist and in some remote and isolated areas. Active sounding rocket ranges within the United States, for example, include White Sands, New Mexico, at the

site of the first atomic weapons tests, Wallops Island, Virginia, on the east coast of the Delmarva Peninsula, and Poker Flat, Alaska, located just north of Fairbanks.

An unusual chapter in the history of the sounding rocket program occurred in the late 1950s and early to mid-1960s when gun-launched payloads were developed and used. Both 5-inch and 16-inch guns were built. The latter consisted of two 16-inch Navy ship gun barrels welded end-to-end and reinforced with steel support web to minimize the barrel droop when the gun was elevated. The propulsion was provided by bags of gunpowder of the type used in standard artillery firings. Since there was no need for a rocket motor, the vehicle consisted of the payload only. The primary launch sites were the island of Barbados in the Caribbean and the test facility at Yuma, Arizona, although some tests of the smaller gun were also carried out at the NASA facility at Wallops Island, Virginia. The 16-inch gun in particular provided a simple and relatively inexpensive system for getting payloads into the ionosphere. In addition to the relatively low cost, the other primary advantage of the system was that a series of launches could be carried out in rapid succession. It was estimated that the gun could be cleaned and reloaded in a little over half an hour. A number of experiments were carried out in which payloads were launched at 1–2-hour intervals throughout the night. The main disadvantage of the gun-launch approach was that the payload accelerations, i.e., *g*-forces, during launch were as much as 1000 times greater than those produced by a conventional rocket motor. As a result, there were significant ongoing problems with telemetry systems and even the simplest type of instrumentation, and there was only limited success. The most fruitful use of this technique was for chemical tracer release experiments which provide a visual means for tracking the movement of the atmosphere, i.e., the winds, and do not require electronics. More than 65 wind profile measurements using trimethyl aluminum (TMA) as a tracer of the neutral flow were carried out from Barbados alone. By the mid-1960s there was heavy emphasis on the use of more conventional rocket motor systems which allowed more complicated and fragile electronics to be used, and the gun launch program was brought to a close. Recently there has been some renewed interest in the technique because of the relatively low cost and because smaller and much more rugged electronic devices are possible now with the integrated systems that can be made using modern solid-state electronics.

Techniques

Although sounding rockets have been a common element in a number of middle and upper-atmosphere studies since the program started after World War II, the instrumentation used on the rockets has varied greatly. In fact, the number of techniques is too large to list them all here. Some of the more common and representative measurements will be described, however.

The majority of the payload instruments used make measurements with an electronic sensor and relay the measured value to a receiving station on the ground via a telemetry radio link. In the early days of the program, analog modulation of the radio signal was used to relay the information. Telemetry systems have evolved together with digital electronics, and

modern systems now transmit information as digitally encoded signals at kilohertz and even megahertz rates.

Examples of electronic instruments used on rocket payloads can be as simple as a thermistor for measuring temperatures or more complicated, such as a Langmuir probe for measuring electron densities, a double probe for measuring the strength of the electric field, or a mass spectrometer for measuring the composition of the neutral or ionized component of the atmosphere. These techniques will be described in more detail below.

Temperature Profile Measurements

One objective of the sounding rocket program from the earliest days in the late 1950s was to develop an inexpensive vehicle that could carry meteorological instruments above 30 km, the maximum altitude of balloon flights. Prior to 1970, the Arcasonde was used extensively. After 1970 the Super Loki, which is less wind-sensitive at takeoff than the Arcas, was used almost exclusively. These small rockets can easily be handled by one person and can carry a payload of a few kilograms to altitudes of 90 to 95 km. The relatively simple and inexpensive vehicles have been used extensively for routine sampling of the stratosphere and mesosphere to obtain density, temperature, and wind profiles. The actual measurement is usually made on the downward portion of the flight and is telemetered, i.e., sent by radio waves to a receiver on the ground. The temperature system is based on a decelerator called a 'Starute' that is released at apogee. The Starute is a combination of an inflatable sphere with an inflatable torus surrounding the center to enhance the stability of the platform as it descends. The payload consists of a bead thermistor to measure the temperature profile. The wind profile is estimated by tracking the horizontal movement of the Starute with radar during the descent.

Electron Density Profile Measurements

One of the earliest instruments flown on sounding rockets was the Langmuir probe, which is used to measure the electron density profile in the atmosphere. The first flight was in the late 1940s, and the same instrument is still used today in many payloads, although with improvements in the electronic design. The probe consists of an electrode with an applied potential that is inserted into the plasma. The current flowing from the plasma to the electrode is then measured. Since the current density is related to the plasma density, the current measurement can be converted to an ambient plasma density value. In the Langmuir probe measurement, the voltage is often swept over a range of values and the voltage-current characteristic of the probe is measured. By sweeping the voltage, both the electron density and the electron temperature can be measured.

Although the basic principle of the Langmuir probe is simple, there are numerous complications in the design of an actual instrument. The shape of the electrode can affect the measurement. Variations in the conductivity of the electrode due to imperfections in the metal or contaminants on the surface can bias the measurements. Effects of the flow past the electrode due to the orientation of the sensor relative to the rocket orientation can also affect the measurement.

Electric Field Measurements

A type of instrument used extensively to measure electric fields in the atmosphere is the double probe, which has what are essentially two Langmuir probes at floating potential. Generally these are pairs of conducting spheres on nonconducting booms deployed symmetrically about the spacecraft. For a body immersed in a plasma, the floating potential is such that the net current to the body is zero. If a background electric field exists in the medium then a potential difference will be induced between the sensors. In reality, the potential difference has contributions from both the ambient field and the field generated by the motion of the sensor system across magnetic field lines. If the motion of the rocket is known accurately, that contribution to the measured potential difference can be subtracted, thus giving a measurement of the ionospheric electric field. Complications include the effects of potentials induced by photoemissions. The latter will cancel if the sensors are completely symmetric and if the conducting surfaces are as uniform and similar as possible. Other potential problems include the effects of the rocket wake and the currents drawn by the voltmeter used to measure the potential difference.

Composition Measurements

Mass spectrometers have been used extensively throughout the history of the sounding rocket program to measure the composition or concentration of various constituents in the atmosphere. The basic instrument is an adaptation from particle accelerator techniques used in the laboratory. Charged particles are allowed to enter the instrument through an aperture on the surface of the rocket payload. As the particles traverse the instrument chamber, their path can be changed by applying electric or magnetic fields within the chamber, and the actual trajectories will depend on the charge to mass ratio. By varying the fields appropriately, the trajectories can be changed so that only the particles with a certain charge-to-mass ratio strike the detector. The measured current is then proportional to the number of particles. The technique obviously requires that the particles be charged, which would be the case for ions. A neutral mass spectrometer operates on the same principle, but the gas particles entering the chamber are charged first by exposing them to an ion source near the aperture.

Potential problems arise if the density of the gas entering the instrument is too high, since collisions can occur between particles so that the trajectories are altered. A typical operating pressure is 1.333×10^{-4} hPa, which is achieved only at altitudes far above 100 km. Measurements at lower altitudes require that the pressure inside the mass spectrometer be pumped down to the appropriate level. The first instrument with a high-speed cryopump to measure the ion concentration and composition in the middle and upper atmosphere was already flown in 1963.

Photometer Measurements

Photometer measurements rely on the natural light emissions from atmospheric gases to infer the density profile of the

emitting gases. When an atom or molecule is excited by absorption of solar radiation, collisions, or chemical processes, it produces light in a very narrow spectral range as it relaxes to a less excited state. Since each kind of molecule or atom has very specific transitions, the intensity of the light that is measured also gives a measure of the total number of atoms that are emitting. A photometer mounted so that it looks toward zenith as the rocket flies through the atmosphere will measure the contribution from all the emitters located above the rocket at any given instant. This information can be used to construct a profile of the number of emitters as a function of altitude.

By using liquid nitrogen to cool the photometers, the background noise in the instruments can be reduced considerably, and photomultiplier tubes can be used to boost the signal detectability. Such modern improvements in the instrumentation have resulted in extremely sensitive instruments with large dynamic ranges.

Other Techniques

There are a few techniques that do not rely on telemetry. One used extensively is the chemical release technique in which a chemical tracer is released from the rocket payload as it traverses a range of altitude in the atmosphere. The tracer is then tracked photographically from two more sites on the ground so that triangulation techniques can be applied to the combined photographic or video image data in order to determine the motion of the tracers. Some of the chemicals that have been used include barium, strontium, lithium, sodium, and trimethyl aluminum (TMA). All of these produce a visible cloud or trail than can be seen with the naked eye in nighttime conditions and therefore can be photographed with reasonably short exposures of a few seconds' duration. The star background in the photographs is used to determine the look direction to the tracer from a given site. The look direction information from several sites can then be combined to give the absolute location of the tracer at a given instant, and the change in position with time gives the velocity.

The various tracers used extensively include barium, which ionizes when exposed to sunlight and thus provides a way to track the motion of ionization in the ionosphere. Since the barium released has to be in sunlight but the observer has to be in darkness in order to be able to see the tracer, such experiments are usually carried out at twilight when those conditions are fulfilled. The barium is mixed with explosive that is detonated to produce a cloud release that appears red to the observer. Lithium and sodium produce resonant scatter that are red and green, respectively, when exposed to sunlight, but both remain neutral and thus provide a means of tracking the nonionized component of the atmosphere. The payload consists of thermite mixed with the chemicals that is ignited to start the release. The burn raises the temperature of the metals sufficiently to vaporize them so that the material is released as a vapor trail along the rocket trajectory. As with barium, the requirement for sunlight limits the time of the measurements to twilight.

The tracer used in more payloads than perhaps any other is trimethyl aluminum (TMA). The chemical has the property that it reacts spontaneously with oxygen or water. At surface

pressures and densities, TMA produces a rapid burn when exposed to oxygen in the atmosphere, but at altitudes in the ionosphere where the oxygen density is much lower the reaction is much slower. The resulting chemiluminescence is bright enough to be seen with the naked eye at night for 5 minutes or longer. Since TMA is neutral, measurements of the wind profiles can therefore be obtained at any time during the night, not just at twilight.

Another type of measurement uses radio beacons to measure the total electron content between the rocket and a receiver on the ground. Beacon systems operate on the principle that the effective path length between a radio transmitter and a receiver are affected by ionization in the intervening region. Specifically the refractive index in a plasma is less than the refractive index of free space, so that fluctuations of integrated electron density induce different variations in the phase path at each frequency. By using dual-frequency radio transmitters on a rocket and measuring the difference in the phase of the two received signals on the ground, the total electron content along the path between the rocket and the receiver can be determined. By making measurements of the phase difference throughout the flight of the rocket, information about both the horizontal and the vertical gradients in the electron densities can be obtained. No telemetry is required for this instrument.

Conclusion

Much of what was learned about the upper atmosphere during the first few decades after World War II was discovered as a result of sounding rocket measurements. More recently satellite technology has become increasingly important for making extensive measurements from the upper troposphere to the lower thermosphere and extending to the upper part of the thermosphere in some cases. The suborbital sounding rockets continue to fill a special niche by covering the gap between the measurements provided by various ground-based remote sensing techniques and sensing satellite measurements both *in situ* and remote. The sounding rocket experiments flown today can be justified on the basis of the science objectives alone, but the sounding rocket payloads are also a relatively inexpensive testbed for instrumentation that can later be flown on satellites. Sounding rockets thus continue to provide a method for obtaining high-resolution *in situ* measurements in near space at relatively low cost. The obvious limitations are the requirement for a rocket range where the vehicles can be launched safely and can impact without danger to either the public or property, and the relatively short duration of the measurement.

Introduction

This article will discuss first what is meant by the term ocean circulation; second, how the ocean circulation is determined by measurements and dynamical processes; and finally, the consequences of this circulation on the Earth's climate.

What is Ocean Circulation?

The ocean circulation in its simplest form is the movement of sea water through the ocean, which principally transfers temperature and salinity from one region to another. Temperature differences between regions give rise to heat transfers. Similarly, differences in salinity produce transfers of salt. On the time scale of the ocean circulation, the inputs and exports of salt into and out of the ocean make a negligible contribution to overall salinity and so variations in salinity occur by the addition and removal of fresh water into and out of the ocean.

Two major processes control the ocean circulation: the action of the wind and the action of small density differences within the ocean, produced by differences in temperature and salinity. The former process is the wind-driven circulation, while the latter is the thermohaline circulation. Although it is useful to separate these two processes to better understand the ocean circulation, they are not independent from each other.

The ocean circulation is in reality a very complex system, because the flows are not steady in time or space. They are turbulent flows that show variability on scales from the largest scale of the ocean basins to the smallest scales where the energy is finally dissipated as heat. This turbulent structure of the ocean means there are fundamental limitations on the predictability of its behavior.

Because of this inherent complexity, oceanographers have approached ocean circulation by using a combination of

observational methods, including ships, buoys, and satellites, combined with the mathematical methods of dynamical oceanography. This integrated approach allows hypotheses to be made that can be tested by comparison with observations. Furthermore, mathematical models of the ocean circulation, based on the dynamical principles, can be constructed and tested against observations.

This article will consider how we measure ocean circulation, how we determine the major processes at work, and the consequences of the ocean circulation on the climate system.

How Do We Determine the Ocean Circulation?

The determination of ocean currents involves measurement of the displacement of an element of fluid over a measured time interval. The position of the measurement is defined mathematically in a Cartesian coordinate system (**Figure 1**) in which x is positive eastward direction (lines of constant latitude), y is positive northward direction (toward the geographic North Pole), and z is positive upward; $z = 0$ corresponds to mean sea level. Without ocean currents and tides, the sea level would be an equipotential surface – that is, one of constant potential energy. The z coordinate is perpendicular to the equipotential surface. The origin is the intersection of the Greenwich meridian (Universal meridian) and the Equator with mean sea level.

The coordinates of a parcel of water may be determined by the Global Positioning System (GPS). This satellite-based system provides a horizontal position with an accuracy of better than 100 m, which is sufficient for large-scale flows in the ocean. Large-scale flows are at least 10 km in spatial scale and have time scales of at least a day. A pressure device attached to a current meter normally determines the vertical position.

There are two mathematical methods for defining the displacement of the fluid. One is to measure the velocity of the

Figure 1 (a) Eulerian and (b) Lagrangian specifications of flow. For both systems, $+x$ is the eastward direction, $+y$ is the northward direction, and z is vertically upward. (a) The Eulerian specification involves measurement of the velocity ($\mathbf{v}$) of the fluid at a fixed point (x, y, z) . (b) The Lagrangian specification involves measurement of the velocity of a fluid element: $\mathbf{a}$ is the position vector from the origin to the fluid element. An element of fluid moves a small distance $\delta \mathbf{a}$ in a time δt , from P to P' . Velocity is $\delta \mathbf{a} / \delta t$. In the infinitesimal limit, $\delta \mathbf{a} / \delta t \rightarrow d\mathbf{a} / dt = \mathbf{v}(\mathbf{a}, t)$.

fluid at a fixed point in the ocean, and the other is to follow the element of the fluid and to measure its velocity as it moves through the ocean. The first method is known as an Eulerian description and the second is a Lagrangian description of flow. In principle, the two methods are independent of each other. This means that an Eulerian measurement cannot provide Lagrangian currents, nor can Lagrangian measurements provide Eulerian currents.

Having defined the two mathematical methods, we will now consider how we can measure currents in practice. Initially, these methods will address only the measurement of the horizontal flow. The vertical flow is difficult to measure directly, and will be discussed later in this article.

First we will consider the Eulerian method. The measurement of the flow at a fixed point in the ocean is only straightforward when a fixed position can be maintained, for instance when a current meter attached to the bottom of the ocean or to a pier on the coast. Most measurements have to be made well away from land. This is achieved by attaching the current meter to a mooring, which is attached to weights and then deployed (Figure 2). The position of the mooring can be determined from GPS. The current meter may be a rotary device or an acoustic device. The rotary current meter measures the number of revolutions over a fixed period, while the acoustic type measures the change in frequency of an emitted sound pulse caused by the ocean current (i.e., it uses the Doppler effect). Moorings may be deployed for periods of up to 2 years. In the analysis of the record, it is normal to remove the high-frequency variability of less than 1 day, caused by tides, by filtering of the data.

A Lagrangian measurement of current can be determined by following an element of water with a float. The horizontal displacement of the water over a small interval of time defines the Lagrangian current. Figure 3 shows typical float designs. The position of the float can be determined by two methods. A float that has a surface satellite transmitter/receiver can have its position determined by GPS, while a subsurface float would use an acoustic navigation system. Some floats can descend to a predetermined depth, maintain that depth for a few weeks and then return to the surface for a position fix. This technique

Figure 2 A typical current meter mooring.

allows the current to be measured down to depths of 1 km below the surface.

Each method gives different information on the flow field. A mooring will give a time series of the horizontal current, whereas a float will give the trajectory of the horizontal displacement of the parcel. It is worth remarking that most of the information on the surface ocean circulation has come from mariners' observations of the ships set, a method that has been used since the nineteenth century. However, these

Figure 3 A typical drifter with a parachute drogue at a few meters below the surface. It will follow the current at the depth of the parachute.

measurements have their limitations since they are neither Eulerian nor Lagrangian measurements and additional influences (e.g., wind effects on the ship) may cause errors.

This information can be analyzed in many different ways to discern the major current systems. From a set of moorings deployed for a few years across, say, the Gulf Stream, we can determine the mean flow (i.e., the average of all the current measurements) and we can determine its variability. The mean flow could be calculated over a particular period of time. This period is limited by the period of deployment, which is of the order of 2 years. This is rather short for a climatological mean, and a much longer period of 10 years is desirable. A few longer time-series of currents have been determined for the Gulf

Stream in the Florida Straits and for the Antarctic Circumpolar Current in the Drake Passage.

Recall that ocean currents are turbulent and therefore have variability on a whole range of time scales. Hence the mean flow gives no information on the variability of the flow. However, we can calculate the statistics of the flow, based on the kinetic energy.

The kinetic energy (KE) per unit volume is defined as in eqn [1].

$$KE = \frac{1}{2} \rho (u^2 + v^2) \quad [1]$$

In eqn [1], ρ is the density of the sea water and u and v are the eastward and northward components, respectively, of the horizontal flow.

If the time mean current is defined as $\bar{u}$, and the deviation from $\bar{u}$ at any time as u' , we can define the mean kinetic energy (KEM) and eddy kinetic energy (EKE) by eqns [2] and [3]

$$KEM = \frac{1}{2} \rho (\bar{u}^2 + \bar{v}^2) \quad [2]$$

$$EKE = \frac{1}{2} \rho (u'^2 + v'^2) \quad [3]$$

These two numbers give quantitative measures on the mean and variability of the flow respectively. The ratio EKE/KEM gives a measure the relative variability of the flow. If the ratio is very much less than 1 then the flow is steady; if the ratio is approximately equal to 1 then the flow is very variable. Figure 4 shows the variability of the flow in the Agulhas Current, which is an intense and highly variable current off the coast of South Africa.

Although the EKE/KEM ratio gives a measure of the variability of the current, it does not give any idea of the exact time or space scales over which the current is varying. For example, the current may show a slow change from one season to another or it may show faster variation due to eddies. To address this variation we can use time-series analysis, such as Fourier analysis, to determine the KE of the flow for different time periods. Fourier analysis produces a spectrum of the KE, either in frequency for a time-series or in wavenumber for a spatial variation in flow. Figure 5 shows the analysis of a time-series into its component frequencies. If the current were varying on all time scales, the spectrum would be flat; if there were only one dominant period, the spectrum would peak at that one frequency. This particular analysis shows that the current is varying at the tidal frequency and the inertial frequency, both at the high-frequency end of the spectrum. The inertial frequency is given by $2\Omega \sin \phi$, where Ω is the rotation rate of the Earth and ϕ is the latitude. At the lower-frequency end, which corresponds to the ocean circulation frequency, there is a broad band of high kinetic energy. This band is due to eddies that cause fluctuations of currents on time scales of weeks to months.

For these mean climatological currents, our knowledge has been augmented by the application of the dynamic method. This method is based on the observation that large-scale ocean currents are in geostrophic balance over large areas of the ocean. Geostrophic balance means that the Coriolis force balances the horizontal pressure gradient force. The geostrophic flow is a good approximation to the flow in the

Figure 4 The mean kinetic energy (KEM) and the eddy kinetic energy (EKE) in a north-south slice through the Agulhas Current System at 14.4° E. Contour units are $\text{cm}^2 \text{s}^{-2}$. The KEM maximum corresponds to the mean position of the Agulhas Return Current (eastward flow) between 40° and 41° S, and the Agulhas Current (westward flow) between 37° and 38° S. The EKE distribution is much broader than that of KEM, which shows the large horizontal extent of the flow variability. The ratio EKE/KEM is typically about 1/3, which indicates a very variable current system. Reproduced from Wells NC, Ivchenko V, and Best SE (2000) *Journal of Geophysical Research* 105, 3233–3246.

interior of an ocean outside the equatorial region. The horizontal pressure gradient is dependent on the slope of the ocean surface and the horizontal variation of the density distribution within the ocean. The geoid is an equipotential surface that would be represented by the sea level of a stationary ocean; ocean currents cause deviations in sea level from the geoid. In the future, the slope of the ocean surface may be determined by satellite measurements of the sea surface height and the geoid, but at present we do not have an accurate geoid at sufficiently

Figure 5 Frequency spectrum of kinetic energy from four depths at Site D (39° N, 70° W), north of the Gulf Stream. Note the two high-frequency peaks, coinciding with the inertial period (19 h) and the semidiurnal tide (12.4 h). Reproduced from Rhines PB (1971) *Deep Sea Research* 18: 21–26.

high resolution to measure the sea surface slope. The horizontal variation of density can be determined from temperature, salinity, and pressure measurements that have been made over large ocean areas during the last century. The dynamic method allows determination of the vertical shear of the horizontal geostrophic current; therefore, additional measurements are required to determine the absolute geostrophic current. For example, if the current has been measured at a particular depth, the dynamic method can be referenced to that depth and the vertical profile of current can be obtained.

The recent World Ocean Circulation Experiment (WOCE) hydrographic program has provided more measurements of the ocean than all the previous hydrographic programs and will give the most comprehensive assessment of the climatological horizontal ocean flow to date.

Recall that we cannot measure the vertical circulation of the ocean directly because it is technically too difficult to do so at present. Current indirect methods used to determine the vertical circulation rely on the use of mathematical approaches, such as dynamical models, or the use of chemical tracers.

Observations of temperature and salinity can be inserted into a mathematical ocean general circulation model (see Box 1) which allows the 3D circulation to be determined, subject to limitations in the accuracy of the model.

Figure 7 A schematic of the model boxes in an ocean general circulation model. The equations for momentum are solved at corners of the boxes (u), while the temperature (T), and salinity (S) equations are solved at the centers of boxes. The model is forced by climatological wind stress, surface heat fluxes, and fresh water fluxes. Reproduced from Summerhayes CP, and Thorpe SA (1996) *Oceanography: An Illustrated Guide*. London: Manson Publishing.

Chemical tracers have been injected inadvertently into the ocean from nuclear tests in the 1960s and from industrial processes (e.g., chlorofluorocarbons). Naturally occurring tracers such as ^{14}C also exist. These tracers can be measured with high accuracy in a few laboratories around the world and, from their distributions at different times, the 3D circulation

can be estimated. This method reveals the time history of the ocean circulation wherever the tracer is measured. This is very different information from that provided by the methods previously discussed, but nonetheless it can reveal unique aspects of the flow. For example, nuclear fallout deposited in the surface layer of the Nordic seas in the 1960s was located in the deep western boundary current 10 years later.

Wind-Driven and Thermohaline Circulation

The wind-driven circulation is considered first. The surface layer of the ocean is directly driven by the surface wind stress and is also subject to the exchange of heat and fresh water between ocean and atmosphere. This layer, which is typically less than 100 m in depth, is referred to as an Ekman layer. A steady wind stress causes a transport of the surface water 90° to the right of the wind direction in the Northern Hemisphere and 90° to the left in the Southern Hemisphere because of the combined action of the wind stress on the ocean surface and the Coriolis force. These Ekman flows can converge and produce a downwelling flow into the interior of the ocean. Conversely, a divergent Ekman transport will produce an upwelling flow from the interior into the surface layer (see [Figure 8](#)).

This type of flow is known as Ekman pumping, and is directly related to the Curl of the wind stress. It is of fundamental importance for the driving of the large-scale horizontal circulation in the upper layer of the ocean. For example, between 30° and 50° latitude the climatological westerly wind drives an Ekman flow equatorward, while between 15° and 30° latitude the Trade Winds drive an Ekman flow polewards. At about 30° latitude the flows converge and sink into the deeper ocean. Before we can discuss the influence of Ekman pumping on the interior ocean circulation, we need to consider role of density.

Box 1 An Ocean General Circulation Model

An ocean general circulation model comprises a set of mathematical equations that describe the time-dependent dynamical flows in an ocean basin. The basin is discretized into a set of boxes of regular horizontal dimensions but variable thickness in the vertical dimension. The horizontal flow (northward and eastward components) is predicted by the momentum equation (Figure 6(a)) at the corners of each box (Figure 7).

The forcing for the flow may come from the wind stress (the frictional term in the momentum equation) and from the surface buoyancy fluxes, arising from heat and fresh water (precipitation+runoff-evaporation) exchange with the atmosphere and adjacent land masses. These buoyancy fluxes change the temperature and salinity in the surface layer of the ocean. The surface water masses are then subducted into the interior of the ocean by the vertical and horizontal components of the flow, where they are mixed with other water masses.

The processes of transport and mixing are described by the temperature and salinity equations (Figure 6(b) and 6(c)) at the center of each ocean box (Figure 7). From these two equations, the sea water density, and thence the pressure, can be obtained for each box. The horizontal pressure gradient is then determined for the momentum equation, while the vertical velocity is calculated from the horizontal divergence of the flow. This set of time-dependent equations can then be used to describe all the dynamical components of the flow field, providing suitable initial and boundary conditions are specified.

Figure 8 A schematic representation of the wind-driven circulation in the subpolar and subtropical gyre of an ocean basin. The wind circulation causes a convergence of Ekman transport to the center of the subtropical gyre and downwelling into the interior. Conversely, in the subpolar gyre there is a divergence of the Ekman transport and upwelling from the interior into the surface layer. This Ekman pumping is responsible for the gyre circulations (see text for details). The western boundary currents are depicted by the closeness of the streamlines. They are caused by the poleward change in the Coriolis force known as the beta effect. Reproduced from Bean MS (1997) PhD thesis, University of Southampton.

As we move from the surface to the deepest layers of the ocean, the density of sea water increases. From hydrographic measurements of density, we can map the horizontal variation of the depth of a chosen density surface. These constant-density surfaces are known as isopycnals. They have the important property that the flow tends to move along these surfaces and therefore the variations in the depth of these surfaces gives us a picture of the horizontal flow in the deep ocean, away from the surface layer and benthic layer. The isopycnal surfaces dip down in the center of the subtropical gyre at about 30° . The formation of this lens of light warm

water is related to the climatological distribution of surface winds, which produce a convergence of Ekman transport toward the center of the gyre and a downwelling of surface waters into the interior of the ocean. At the center of the lens, the sea surface domes upwards, reaching a height of 1 m above the sea surface at the rim. Owing to hydrostatic forces, the main thermocline is depressed downward to depths of the order of 500–1000 m (Figure 9).

The surface horizontal circulation flows anticyclonically around the lens with the strongest currents on the western edge, where the slope of the density surface reaches a maximum.

Figure 9 A representation of the meridional average section through the atmosphere for December–February. The cells are the Hadley cell (H) and the Ferrel cell (F). The strength of the cells is represented by the solid contours which are in units of 40 Mt s^{-1} , whilst the dashed contours are in units of 20 Mt s^{-1} . Note the predominantly downward motion at $\sim 30^\circ$ latitude, associated with the subtropical anticyclones, and the strong upward motion at equatorial latitudes which is associated with the Inter-Tropical Convergence Zone. A meridional transect through the Atlantic Ocean, showing the position of the main thermocline. The small arrows represent the wind driven downwelling (Ekman pumping) at $\sim 30^\circ$ latitude, and the equatorial upwelling, which occurs within and above the main thermocline. The North Atlantic Deep Water (NADW) is produced in the Nordic Seas and is the predominant water mass by volume. The Antarctic Intermediate Water (AIW) is produced at $\sim 50^\circ \text{ S}$ and by virtue of its salinity is lighter than the NADW. In contrast Antarctic Bottom Water is the most dense water mass in the world's ocean and is formed in the Weddell and Ross Seas. These deep flows form part of the thermohaline circulation. The vertical scales are exaggerated in the lower troposphere and in the upper ocean. The horizontal scale is proportional to the area of the Earth's surface between latitude circles.

These are geostrophic currents, where there is a balance between the Coriolis force and the horizontal pressure gradient force. Generally, the circulation in the subtropical gyres is clockwise in the Northern Hemisphere and anticlockwise in the Southern Hemisphere. These large-scale horizontal gyres are ultimately caused by the climatological surface wind circulation and are found in all the ocean basins.

The surface layer is also subject to heating and cooling, and the exchange of fresh water between ocean and atmosphere, both of which will change the density of the layer. For example, heat is lost over the Gulf Stream on the rim of the light water lens of the subtropical gyre. Recall that flow tends to follow isopycnal layers and these layers will slope downward toward the center of the gyre. Cooling of the waters in the Gulf Stream leads to the sinking of surface waters to produce a water mass known as 18°C water. This water, which is removed from the surface layer, will slowly move along the isopycnal layers into the thermocline. As it moves clockwise around the gyre it will be subducted in to the deeper layers of the thermocline, in a spiral-like motion (Figure 8). The deepest extent of the main thermocline is located in the subtropical gyre to the west of Bermuda on the eastern edge of the Gulf Stream rather than in the center of the ocean basin. This asymmetry of the gyre is related to the beta effect – the change of the Coriolis parameter with latitude.

The subtropical gyres are one of the best-studied regions of the ocean, and our understanding is therefore most developed in these regions. These gyres occur in the surface and thermocline regions of the ocean and are primarily controlled by the wind circulation, with modifications due to heating and cooling of the surface. The question now arises why we observe thermoclines in the ocean. For example, why is the warm water not mixed over the whole depth of the ocean and why is the average ocean temperature about 3°C .

To explain the observed behavior, we need to consider the thermohaline circulation, which is generated by small horizontal differences in density, due to temperature and salinity, between low and high latitudes. How does it work? Consider an ocean of uniform depth and bounded at the Equator and at a polar latitude. We will assume it has initially a uniform temperature and is motionless (we will ignore for the moment the effect of salinity on density). This hypothetical ocean is then subject to surface heating at low latitudes and surface cooling at high latitudes. In the lower latitudes the warming will spread downward by diffusion, while in high latitudes the cooling will spread downward by convection, which is a much faster process than diffusion. The heavier, colder water will induce a higher hydrostatic pressure at the ocean bottom than will occur at low latitudes. The horizontal pressure gradient at the ocean bottom is directed from the high latitudes to the lower

latitudes, which will induce an equatorward abyssal flow of polar water. The flow can not move through the equatorial boundary of our hypothetical ocean and therefore will upwell into the upper layer of the tropical ocean, where it will warm by diffusion. The flow will then return poleward to the high latitudes, where it downwells into deepest layers of the ocean to complete the circuit. It is found that the downwelling occurs in narrow regions of the high latitudes, while upwelling occurs over a very large area of the tropical ocean. This hypothetical ocean demonstrates the key role of the deep horizontal pressure gradient, caused by horizontal variations in density, for driving the flow.

To explain the observed thermohaline circulation, this hypothetical ocean has to be modified to take into account the Coriolis force, which causes the deep abyssal currents to flow in narrow western boundary currents, the effect of salinity on the density (the haline component of the flow), asymmetries in the buoyancy fluxes between the Northern and Southern Hemispheres, and the complex bathymetry of the ocean basins.

We will now give a descriptive account of the thermohaline circulation. The deepest water masses in the ocean have their origin in the polar seas. These seas experience strong cooling of the surface, particularly in the winter seasons. In the North Atlantic, there are connections through the Nordic seas to the Arctic Ocean, through which sea ice flows. Heat energy melts the ice in the North Atlantic and the meltwater gives rise to further cooling. There are two effects on the density of the water: Cooling increases the density whereas surface freshening, due to ice melt, decreases the density of the water. The former process usually dominates the density and hence denser waters are produced. These dense, cold waters flow into the Atlantic through the East Greenland and West Greenland Currents and then into the Labrador Current. These cold waters mix and sink beneath the warm North Atlantic Current.

In addition to surface polar currents, we also have deep ocean currents. The cold saline water entering from the Nordic seas mixes as it sinks to the abyssal layers of the ocean and moves southward as a deep current along the western boundary of the Atlantic. This water mass is known as NADW (North Atlantic Deep Water) and is the most prominent and voluminous of all the deep water masses in the global ocean. It flows into the Antarctic Circumpolar Current, from where it flows into the Indian and Pacific Oceans. In addition to NADW, colder denser water – Antarctic Bottom Water (AABW) – enters the Southern Ocean from the Antarctic shelf seas. It is not as voluminous as NADW but it flows northward in the deepest layers into the Atlantic, where it can be distinguished as far north as 30°. These deep flows upwell into the thermocline and surface waters where they return to the North Atlantic. This global thermohaline circulation has been termed the global conveyor circulation to signify its role in transporting heat and fresh water (Figure 10) around the planet.

How does this circulation explain the thermocline? We can estimate the rate at which these cold, deep abyssal waters are produced and we know for a steady state in the ocean that production has to be balanced by removal. A large-scale upwelling of the abyssal waters into the thermocline produces this removal. Our simple conceptual picture is of warm thermocline water mixing downward, balanced by a steady upwelling of the cold abyssal layers. Without the

upwelling, the warm waters would mix into the deepest layers of the ocean.

The Role of Fresh Water in Ocean Circulation

In the discussion so far we have seen that the wind-driven circulation and the thermohaline circulation are major components of ocean circulation, which are ultimately driven by the surface wind stress and buoyancy fluxes. Buoyancy fluxes are the net effect of heat exchange and the fresh water exchange with the overlying atmosphere. We have seen that heat exchange is a major process explaining the existence of both the thermocline and the deep abyssal water, but what is the role of the fresh water in ocean circulation?

In the subtropics there is net removal of fresh water by evaporation. This increases the salinity of the water, which, in turn, increases the density of the thermocline waters. Normally this effect is opposed by heating, which lightens the water. However, in the Mediterranean and the Red Sea, evaporation produces saline waters, which by virtue of their salinity and cooling in winter, sink to the deepest layers of the basins. At the Straits of Gibraltar, this dense saline layer flows out beneath the incoming fresher and cooler Atlantic water. This Mediterranean water forms a distinct layer of high-salinity water in the eastern Atlantic Ocean. Similar behavior occurs at Bab el Mandeb adjacent to the Gulf of Aden.

The influence of fresh water is more substantial in the polar oceans. A given amount of fresh water will have a greater effect on density at low temperatures than at high temperatures, because the thermal expansion of sea water decreases with decreasing temperature. At higher latitudes, we have a net addition of fresh water into the oceans, which arises from the excess of precipitation over evaporation and the melting of sea ice moving toward the Equator from the polar regions.

The addition of fresh water adds buoyancy to the surface layer, while cooling removes buoyancy; therefore, the fresh water will tend to reduce the effect of the cooling. In the Arctic Ocean, the surface layer is colder but less dense than the warmer layer at ~100 m and therefore is in equilibrium. This stable halocline in the Arctic Ocean reduces the vertical heat flux into the deep ocean.

In the subpolar oceans, the addition of fresh water reduces the density of the surface layer and can reduce the prevalence of deep convection. This happened in the late 1960s when fresh water, probably from excessive ice in the Arctic Basin, melted in the subpolar gyre. The effect on the thermohaline circulation is unknown, but it is believed from modeling studies that the drop in the production of deep waters reduced the thermohaline circulation of the ocean.

What Are the Consequences of this Circulation on the Climate System?

The effects of the ocean circulation on the climate can be understood in terms of the heat capacity of the ocean. The heat capacity of a column of sea water only 2.6 m deep is equivalent to that of a column of the whole atmosphere and therefore the ocean heats and cools on a long time scale compared with the atmosphere.

Figure 10 (a) Poleward transfer of heat (a) by ocean and atmosphere together ($T_A + T_O$), (b) by atmosphere alone (T_A), and (c) by ocean alone T_O . The total heat transfer (a) is derived from satellite measurements at the top of the atmosphere; that of the atmosphere alone (b) is obtained from measurements of the atmosphere; and (c) is calculated as the difference between (a) and (b). 1 petawatt (PW) = 10^{15} W. (d) An estimate of the transfer of fresh water (10^9 kg s^{-1}) in the world ocean. In polar and equatorial regions precipitation and river runoff exceed evaporation, and hence there is an excess of fresh water, while in subtropical regions there is a water deficit. A horizontal transfer of fresh water is therefore required between regions of surplus to regions of deficit. F_P and F_A refer to the fresh water fluxes of Pacific-Indian throughflow and of the Antarctic Circumpolar Current in the Drake Passage, respectively. (a)–(c) Reproduced from Carrissimo BC, Oort AH, and von der Haar TH (1985) *Journal of Physical Oceanography* 15: 85. (d) Reproduced from Wijffels SE, Schmitt R, Bryden H, and Stigebrandt A (1992) *Journal of Physical Oceanography* 22: 158.

We know that there is poleward gradient of temperature, which is driven by the thermal radiation imbalance between the low and high latitudes. In response to this temperature gradient, we require a flow of heat from the warmer to cooler latitudes. Both the atmosphere and ocean circulations transfer this heat from low to high latitudes by a variety of mechanisms. In the low latitudes of the atmosphere there is the Hadley cell, which transfers low-temperature air in the lowest levels via the Trade Winds toward the Equator and transfers warmer air poleward in the upper troposphere (Figure 9). At higher latitudes, anticyclones and cyclones and their accompanying upper-air jet streams transfer heat poleward. In the ocean, the wind-driven Ekman currents transfer heat as surface waters move across latitude circles. This water is returned deeper in the ocean at a different temperature from that of the surface water. The ocean gyres carry heat toward higher latitudes since the poleward flows of the western part of the gyres are warmer than the equatorward flows in the eastern parts of the gyres. Finally, and not least, there is the contribution of the thermohaline circulation, which transports warm surface and thermocline waters to the highest latitudes and returns cold water to lower latitudes. Figure 10 shows the heat transport and fresh water in the ocean.

A major difference between the atmosphere and the ocean is the relative speed of their circulation. The atmosphere circulation is a fast system, responding on time scales of days to weeks. For example, weather systems in temperate latitudes grow and decay on time scales of a few days. By contrast, the ocean tends to be slower in its response. The fastest parts of the system are the surface Ekman layers, which respond to changes in the surface wind circulation on a time scale of 1 or 2 days. Changes in wind circulation can cause planetary waves that will change sea level and surface temperature on monthly to seasonal time scales. In particular, the equatorial oceans respond to the surface wind stress on seasonal time scales, which allows a strong coupling between the ocean and atmosphere to take place. This gives rise to phenomena such as the El Niño Southern Oscillation. The subtropical gyres respond to changes in the wind circulation on decadal time scales, while the deep thermohaline circulation responds on millennial time scales. There is some evidence for rapid changes of local parts of the thermohaline circulation on time scales of 50 years.

Observations of the deep ocean are far fewer in number than at the ocean and land surface. The longest continuous data set is from a deep station at Bermuda that commenced operations in 1954. Observations from cruises in the earlier part of the century are of unknown quality and it is therefore difficult to know whether differences are due to the use of different instruments or to real changes in the ocean. It is only since the 1950s that such changes have been measured accurately. Figure 11 shows changes in the temperature for that period across the Atlantic. These changes are of the order of a few tenths of a degree over periods of 15 years. Recall that the heat capacity of oceans is very much larger than atmosphere: hence these changes in temperature involve very significant changes in the heat content of the ocean. The World Ocean Circulation Experiment from 1990 to 1997 has provided measurements of ocean properties such as temperature, salinity, and chemical tracers as well as current

Figure 11 Temperature changes (°C) in the subtropical North Atlantic (24° N), 1957–1992. The measurements have been averaged across 24° N between North Africa and Florida. measurements on a global scale. This set of high-quality measurements will provide the baseline from which future changes in ocean circulation can be determined.

In contrast to the brief record of deep ocean observations, sea surface temperature measurements of reasonable quality go back to the late nineteenth century. These measurements can be used to assess changes in the surface layers. Salinity measurements are fewer and not as reliable, but changes can be still detected.

Salinity measurements in the Mediterranean over the last century have shown a warming of the Western Mediterranean Deep Water of 0.1°C and increase of 0.05 in salinity. These reasons for this change are not known, but it has been speculated that the change in salinity may be attributed to a reduction in the fresh water flow due to the damming of the Nile and of rivers flowing into the Black Sea.

An important question recently identified is the stability of the thermohaline circulation. The thermohaline circulation is driven by small density differences and therefore changes in the temperature and salinity arising from global warming may alter the thermohaline circulation. In particular, theoretical modeling of the ocean circulation has shown that the thermohaline circulation may be reduced or turned off completely when significant excess fresh water is added to the subpolar ocean. In the event of the thermohaline circulation being significantly reduced or stopped, it may take many centuries before it returns to its present value.

In view of the current levels of uncertainty, it is necessary to continue to monitor the ocean circulation, as this will provide the key to the understanding of the present circulation and enhance our ability to predict future changes in circulation.

Synopsis

Surface motions in the upper ocean include surface waves and wind-driven currents. These motions are driven by surface winds. There is a wave boundary layer in the upper ocean where surface waves dominate. Below this surface boundary layer, the ocean can be conceptually separated into several layers, including the Ekman layer, the mixed layer and the main thermocline, and the thick layer below. These layers are characterized by different dynamics, but they may overlap. The most outstanding feature is the main thermocline, and it can be treated as the base of the wind-driven circulation in the upper ocean.

Introduction

Winds on the sea surface provide the major source of energy responsible for motions in the upper ocean over broad spatial and temporal scales, from surface waves and small-scale turbulent motions to large-scale oceanic currents. Although people walking on the beach or on board of ships can easily observe surface waves and small-scale turbulence and currents, the large-scale currents can be studied through well-planned scientific observations only. Wind-driven circulation is a key player in regulating the sea surface temperature and the air–sea heat flux; thus, wind-driven circulation is an important component of the climate system. This article is focused on the dynamic structure of the wind-driven circulation; hence, the feedback to the atmosphere is not discussed here.

Wind Stress Pattern

Wind stress on the sea surface is one of the most important driving forces for the oceanic circulation. Wind stress generates small-scale surface waves first; through wave–wave interaction, energy is transferred in phase space, leading to surface waves of long wavelength and large amplitude. However, in comparison with the larger-scale currents, surface waves are considered as small-scale problems and they are not considered as parts of wind-driven circulation discussed in this article.

Winds on the sea surface represent the velocity structure at the base of the atmospheric boundary layer. As such, they are directly linked to the circulation above the atmospheric boundary layer, and their pattern reflects the overall structure of the atmospheric general circulation; thus, they have remarkable global-scale structure, [Figure 1](#), where the annual mean winds stress is displayed. The most outstanding feature of the wind stress over the global oceans is the strong westerlies at midlatitudes of both hemispheres, which is the surface expression of the jet stream of the atmospheric circulation. At low latitudes, the trade wind dominates; at the equator, easterlies dominate in the Pacific and Atlantic Oceans, but in the Indian Ocean relatively weak westerlies dominate.

For a long time, winds were measured through ship-board instruments over the global oceans. Since the advance of satellite technology, wind speed and direction over the global ocean can be directly inferred from microwave measurements

over the sea surface (such as the QuikSCAT data). The common practice in oceanography is to calculate wind stress using the bulk formulae $\tau_w = \rho_{\text{air}} C_d |\vec{u}_{\text{atm}} - \vec{u}_{\text{oce}}| (\vec{u}_{\text{atm}} - \vec{u}_{\text{oce}})$, where ρ_{air} is the air density, $C_d \approx 10^{-3}$ is the empirical drag coefficient, $\vec{u}_{\text{atm}} - \vec{u}_{\text{oce}}$ is the velocity difference between the air and water within the boundary layers. Note that C_d is not a constant, and it varies with the wind speed. The bulk formulae are based on many *in-situ* measurements; however, the accuracy of the bulk formulae remains to be improved, especially for the case with strong wind. In addition, although in many previous applications the effect of oceanic current were not included in the calculation of wind stress, recent studies indicated that the correction due to the ocean current should be taken into consideration.

Wind stress changes with time, and it has a noticeable seasonal cycle over most parts of the world ocean. In particular, seasonal cycle of wind stress in the Indian Ocean and adjacent oceanic regions is quite strong. For example, wind over the Somali and Vietnamese coasts blows in opposite directions during different seasons, [Figure 2](#). The seasonal cycle of wind stress in these areas strongly affects the local upwelling and the strength and direction of coastal currents.

Furthermore, wind energy input into surface waves is a strong nonlinear function of wind stress, so that the high frequency components of wind stress make a critical part of contribution to the wind energy input into the ocean. Although monthly mean wind stress can be used to calculate the wind-driven circulation with reasonable results, mixed layer property calculation requires wind stress products with high temporal resolution up to 6-hourly wind.

Surface Circulation in the World Ocean

Apart from the surface wave boundary, the upmost part of the ocean is occupied by the Ekman layer where the frictional force is balanced by the Coriolis force. Below this relatively thin upper layer, currents in most parts of the world oceans are organized in the form of gigantic gyres, as shown in [Figure 3](#). There are strong subtropical gyres in the North Pacific, North Atlantic, South Pacific, South Atlantic, and the South Indian Oceans. At high latitudes, there are subpolar gyres in the North Pacific and North Atlantic Oceans, and Weddell Sea Gyre and Ross Sea Gyre at the southern edge of the South Ocean.

Figure 1 Annual mean wind stress, based on QuikSCAT data.

Figure 2 Seasonal cycle of wind stress in the (a) Somali coast (at 50.125° E, 5.125° N) and (b) South of Vietnam (at 108.125° E, 10.125° N), based on WOA09 data.

These gyres are directly driven by surface winds. Many oceanic currents observed in the oceans are part of the organized wind-driven circulation discussed in this article, including the Gulf Stream in the North Atlantic Ocean, the Kuroshio in the North Pacific Ocean, the Brazil Current in the South Atlantic Ocean, the East Australian Current in the South Pacific Ocean, and the Agulhas in the Southwest Indian Ocean.

One of the most important features of these wind-driven gyres is the western intensification of the currents,

as schematically shown in [Figure 3](#). Although most currents in the ocean interior move relatively slowly, these western boundary currents can reach the speed in excess of 1 m s^{-1} . Most importantly, they can carry a huge amount of water. For example, the Gulf Stream transports can reach to 150 Sv ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$). In addition, they carry a large amount of heat and thus play a critically important role in setting up the poleward heat transport in the Earth's climate machinery.

Figure 3 Major surface currents in the world oceans.

The fast-moving western boundary currents were discovered long time ago by marine navigators. Benjamin Franklin and Timothy Folger in 1769–70 created the first chart of the Gulf Stream, which was widely used by navigators going on cruises between European countries and North America. Even at the present day, their chart of the Gulf Stream seems quite accurate in prescribing the large-scale feature of this fast-moving current system. The dynamical explanation of such fast-moving currents or the so-called western intensification had to wait for more than 170 years following this chart.

At low latitudes, there are strong equatorial current systems in the Pacific, Atlantic, and Indian Oceans, and they play critical roles in the oceanic circulation and climate system.

There is also a strong Antarctic Circumpolar Current (ACC), which is the only circum-earth current system under the present continental setting. In addition, there are many other surface currents, which connect surface circulation in different parts of the world oceans, such as the Indonesian Throughflow and the North Atlantic Current.

The shape of subtropical gyres is somewhat similar to the pattern of wind stress in the subtropical basins. The similarity between the circulation patterns in the atmosphere and oceans is deeply rooted in the dynamics. In fact, as will be explained shortly, the formulation of the gyration is the consequence of potential vorticity balance in a closed basin; thus, the wind stress curl is the essential ingredient of wind-driven gyres.

Thermal Structure in the Upper Ocean

The circulation in the upper ocean is closely related to the density structure. Seawater density is controlled by temperature and salinity; however, over much of the warm near-surface waters, temperature dominates. Therefore, density structure

can also be inferred from temperature structure in the oceans. There is a mixed layer on the top of the ocean, where the temperature, salinity, and density is vertically nearly homogenized. Water properties and depth of the mixed layer have a profound annual cycle.

The mechanical energy required to sustain the turbulent motions in the mixed layer is provided by the wind stress applied to the sea surface. In particular, wind stress inputs about 60 TW ($1 \text{ TW} = 10^{12} \text{ W}$) of mechanical energy into the surface waves. The exact amount of this energy remains a topic of intensive research, and its pathway in the ocean remains unclear. However, it is believed that most part of this energy is dissipated within the mixed layer, leaving only a quite small portion of it to be transformed into the deeper part of the ocean, probably in forms of near-inertial oscillations. In addition, convection due to surface cooling or salt rejection during sea ice formation can also provide kinetic energy sustaining turbulent motions in the mixed layer. It is to emphasize that, however, the kinetic energy associated with turbulent motions due to convection is converted from the gravitational potential energy originally stored in the system. In fact, convection in the ocean cannot create mechanical energy.

Another outstanding feature in the thermal structure in the upper kilometer of the world ocean is the main thermocline. The thermocline is defined as a layer within the water column where the vertical gradient of temperature is a local maximum. There are four major types of thermoclines in the ocean: diurnal, seasonal, main, and abyssal thermoclines. The diurnal thermocline is associated with the diurnal cycle of the mixed layer and it exists in the upper few tens of meters in the ocean; the seasonal thermocline is associated with the seasonal cycle of the mixed layer, and it extends from the base of the diurnal thermocline to the depth of a couple of hundred meters except

in some special locations where wintertime convection can reach to great depths. The main thermocline is below the seasonal thermocline at depths of 200–800 m. As a result, it is not greatly affected by the seasonal cycle of the mixed layer; hence, it is also called the permanent thermocline. In addition, in part of the world oceans there is abyssal thermocline associated with abyssal circulation.

Wind-driven circulation can exist in either a homogeneous ocean or a stratified ocean. Wind-driven circulation in a homogeneous ocean is very weak because the volumetric flux of the circulation is uniformly distributed over the entire depth of the ocean. On the other hand, due to the existence of strong stratification associated with the main thermocline, wind-driven circulation is mostly confined to an upper moving layer above the main thermocline. As a result, currents associated with wind-driven circulation in a stratified ocean can be greatly enhanced.

In most parts of the world oceans, seawater density is primarily controlled by temperature, with salinity playing a secondary role. Therefore, the main thermocline is also closely linked to the main pycnocline. Note that dynamically the main pycnocline is more directly relevant to the dynamics of the oceanic circulation; however, the main thermocline itself is closely linked to temperature changes in the atmosphere, hence thermocline is a term often used in scientific study of the oceanic circulation and climate changes.

The typical structure of the main thermocline can be seen through an east–west temperature section. As shown in Figure 4, the main thermocline is located around the depth of 200 m at the eastern boundary, and gradually slopes down to the depth of 600 m in the North Pacific Ocean and 800 m in the North Atlantic Ocean. As shown in Figure 4, warm water in the upper ocean is separated from the cold water in the deep ocean by a layer of relative shape temperature gradient associated with the main thermocline.

In the interior part of the ocean, large-scale currents obey geostrophy. Using geostrophy and thermal wind relation, the

direction of large-scale current can be inferred from temperature or density sections as follows. Since strong wind-driven current is confined in the upper kilometer of the ocean, one can assume that water at great depth is motionless. For example, one can assume that horizontal velocity at the depth of 2.5 km is negligible, and the corresponding horizontal pressure gradient is nearly zero at this depth. As shown in Figure 4, water on the right-hand side of the ocean basins is colder and thus denser than that on the left-hand side. Using the thermal wind relation and the hydrostatic approximation, one comes to the conclusion that at depth shallower than 2.5 km pressure gradient force in the oceanic interior is pointed eastward. According to geostrophy, to balance the pressure gradient force the Coriolis force must point westward; thus, current in the ocean interior should move equatorward.

On the other hand, near the western boundary the slope of isopycnal flips sign and becomes quite steep, indicating strong and poleward narrow western boundary currents. Thus, temperature and the corresponding density structure shown in Figure 4 can be interpreted as the sign of the western intensification.

Density structure along the meridional section reveals another important dynamic feature, Figure 5. The center of the wind-driven circulation on each isopycnal surface is roughly the deepest part of the isopycnal surface. As shown in Figure 5, the center of the circulation moves northward with increasing density. This is called the poleward intensification of the wind-driven subtropical circulation. This is also linked to the recirculation of the subtropical gyre, as will be discussed shortly.

In general, near the equator thermocline is much shallower. Since the Coriolis force vanishes near the equator, the equatorial thermocline is directly linked to the equatorial zonal wind stress. In a steady state, at the sea level the zonal wind stress on surface is balanced by the pressure gradient force associated with the zonal sloping sea surface. In both the Pacific and Atlantic Oceans, easterlies prevail near the equator.

Figure 4 Temperature section along 29.5° N, based on WOA09 data.

Figure 5 A potential density section along 48.5° W, based on WOA09 data.

As a result, equatorial thermocline in these two basins slopes downward from east to west. On the other hand, the main thermocline in the Indian Ocean slopes down eastward because wind in the Indian Ocean is primarily westerly. This combination of equatorial winds leads to a condition favorable for the formation of a large warm pool with the main thermocline sits at the depth of 200 m in the western equatorial Pacific. In the east side, there is a cold tongue in both the equatorial Pacific and Atlantic Oceans, upper panel of [Figure 6](#).

In the meridional section, the main thermocline appears in the form of a dumbbell, lower panels of [Figure 6](#). The bowl-shaped main thermocline at midlatitudes in these three basins is outstanding. It is clear that the main thermocline is deepest in the South Indian Ocean. The main thermocline in the North Atlantic Ocean is deeper than that in the North Pacific Ocean.

The depth of the main thermocline in the world oceans is closely linked to the wind-driven circulation in the upper ocean. In the world oceans, there are five subtropical gyres and they can be clearly identified from the basin-scale bowl-shaped main thermocline, as shown in [Figure 7](#). Note that the main thermocline is a conceptual layer only; thus, such a subsurface vertical temperature gradient maximum may not exist at any specific location. As will be shown shortly, the simple reduced gravity model predicts that the depth of the main thermocline is proportional to the zonal integration of the Ekman pumping rate and inversely proportional to the stratification in the upper ocean. For example, in the Pacific Ocean relatively low salinity in the upper ocean leads to a relatively strong stratification in the upper ocean and thus a shallow main thermocline. On the other hand, high salinity water in the Atlantic and Indian Ocean leads to relatively weak stratification and relatively deep main thermocline.

Theory of the Wind-Driven Circulation

Ekman Layer

There is an Ekman layer in the upper ocean. The Ekman layer is defined as the surface boundary layer in which the frictional force is balanced by Coriolis force. Ekman in 1905 first formed the idea of such a boundary layer in the ocean. Winds input a large amount of mechanical energy, on the order of 3 TW, which is used to maintain motions in the Ekman layer against friction. Within the Ekman layer, the wind stress is transformed downward through eddy-induced horizontal momentum flux. A major uncertain part of the Ekman layer theory is the vertical eddy viscosity A_v . The classical theory of Ekman layer assumes that A_v is isotropic and has a constant value over the whole depth of the layer. Under such an assumption, the horizontal velocity for the Ekman layer in a steady state appears in the form of a spiral, quite similar to that in the atmospheric boundary layer.

Observing the Ekman layer in the ocean was a great challenge due to the stance of strong surface waves and turbulence in the upper ocean. Ekman layer predicted by the classical theory was confirmed through observation only in the 1980s. Observations indicated that vertical eddy viscosity A_v is not constant. In fact, *in-situ* observations indicated that vertical eddy viscosity decays with increasing depth following some negative power laws or exponentially decaying laws. If A_v is not constant or isotropic, the shape of the Ekman spiral can be different from that predicted by the classical theory.

The horizontal volume transport integrated over the depth of the Ekman layer is independent of the vertical eddy viscosity; this volume transport is perpendicular to the wind stress and pointing to the right-hand side (in the Northern Hemisphere); it can be written in the form of $\vec{V}_{\text{Ekman}} = -\vec{z} \times \vec{\tau} / f \rho_0$, where τ is the wind stress, f is the Coriolis parameter, ρ_0 is mean water

Figure 6 Temperature section along the equator (a) and meridional section through three basins (b,c,d), based on WOA09 data.

Figure 7 Depth of the main thermocline in the world oceans, based on WOA09 data.

Figure 8 Meridional Ekman transport (a) and Ekman pumping (b) in the world oceans, based on QuikSCAT data.

density. The zonally integrated Ekman transport in the three basins is on the order of 10–20 Sv (Figure 8(a)). As it is inversely proportional to the Coriolis parameter, it becomes unbounded near the equator, indicating that the theory of Ekman layer does not apply to the equatorial band.

Thus, there are large horizontal mass transports in the upper ocean, which can play key roles in transporting heat, fresh-water, and other tracers. Since it is directly proportional to the wind stress, such transports can change in response to variability in the atmospheric circulation and climate.

Due to variation of both wind stress and Coriolis parameter f , Ekman transport varies with geographic location. The convergence (divergence) of Ekman transport leads to the Ekman pumping, $w_{\text{Ekman}} = \text{curl}(\tau/f\rho_0)$. In general, Ekman pumping velocity is quite small, on the order of 10^{-6} m s^{-1} , which is equivalent to 0.08 m per day or 30 m per year. However, in subtropical basin interiors this seemingly small vertical velocity leads to an equatorward geostrophic flow in the subsurface layer, and thus dynamically sets up the gigantic wind-driven circulation in the subtropical basins; while in the subpolar basin, Ekman pumping is upward, and it leads to a poleward geostrophic flow in the subsurface layer and thus the cyclonic subpolar gyres.

Coastal upwelling/downwelling is induced by long-shore wind. If wind blows along the coast, off-shore (or on-shore) Ekman transport must be compensated by upwelling (downwelling) along the coast. Coastal upwelling can bring nutrient-rich water from depth to the surface; thus, high productivity and good fishing grounds along some of the coastlines are closely linked to strong along-shore wind. Since along-shore wind often changes with the season, the strength of coast upwelling also has strong seasonal cycle, and hence the biological productivity. Some of the sites of strongest seasonal cycle of the coastal upwelling are shown in Figure 2. The seasonal cycle of wind stress is strong in the Indian Ocean. In particular, the seasonal cycle of wind stress east of Somalia is very strong, so that coastal upwelling there has a very strong seasonal cycle. In fact, the seasonal cycle of wind is so strong that the direction of the Somali current reverses during the seasonal cycle.

Sverdrup Transport of the Wind-Driven Circulation

The simplest way to describe the wind-driven circulation is to treat the circulation in the upper ocean in terms of a single layer; thus, the wind stress is to be treated as a body force uniformly distributed within this layer. The layer integrated volume flux satisfies the Sverdrup relation:

$$\beta h v = (\partial \tau^y / \partial x - \partial \tau^x / \partial y) / \rho_0. \quad [1]$$

where $\beta = df/dy$, h is the layer thickness, v is the meridional velocity, (τ^x, τ^y) are the wind stress components, and ρ_0 is the constant reference density. The Sverdrup relation is essentially a potential vorticity equation. According to this equation, negative wind stress curl in the subtropical basin drives an equatorward flow in the basin interior. A zonal integration of this relation leads to the Sverdrup streamfunction (or Sverdrup transport). The Sverdrup transport includes contributions due to surface Ekman transport and the geostrophic transport above the thermocline layer. As an example, Figure 9 shows the Sverdrup transport in the Pacific Ocean. There are clearly the subtropical gyres in both the North and South Pacific Oceans, with the maximum streamfunction on the order of 40 Sv. In addition, there is a subpolar gyre at the northern high latitudes and the equatorial circulation system at low latitudes. Note that the Sverdrup relation is valid for the steady state circulation only.

Theories of the Wind-Driven Gyres

The energetics of wind-driven circulation

Wind-driven gyres are the direct result of surface wind forcing. These gigantic circulation systems are sustained by mechanical energy input from the surface winds. Wind energy input to the ocean can be separated into several categories. First and most importantly, the total amount of mechanical energy input to the large-scale surface currents is estimated as 1 TW, and most of such energy is put into the South Ocean and other regions of fast currents, such as the Gulf Stream and Kuroshio. Second, the wind energy input to the Ekman layer is about 3 TW; however,

Figure 9 Sverdrup transport in the Pacific Ocean, based on QuikSCAT data.

most of this energy is used to overcome the friction in the Ekman layer. Third, surface waves receive approximately 60 TW from the surface wind; however, this huge amount of mechanical energy is mostly dissipated within the surface wave boundary layer. There is the Langmuir circulation in the upper ocean, which is closely linked to surfaced waves. Surface waves and Langmuir circulation play key roles in regulating the surface layer dynamics and the air-sea interaction. In addition, a small amount of mechanical energy received by surface waves can penetrate through the base of the mixed layer and thus contribute to mixing in the subsurface layer; but, the pathway and this energy remains unclear at this time. Fourth, the sea level atmospheric pressure varies with time; combining with the vertical motions of the sea surface, this leads to a mechanical energy input to the ocean. The exact amount of this energy input remains unclear, and current estimate puts it on the order of 0.01–0.04 TW. However, the effect of sea level pressure change is mostly projected into the barotropic mode in the oceans; thus, its effect on the surface motions is small and may be negligible.

The reduced gravity model

The structure of the wind-driven circulation can be explored in terms of the simple reduced gravity model. The basic idea is to treat the main pycnocline as a step function in density coordinate. Assume that the upper and lower layers have constant density ρ_1 and ρ_2 , and the lower layer is infinitely deep and motionless. A commonly used parameter in such a model is the reduced gravity, defined as $g' = g(\rho_2 - \rho_1)/\rho_0$. The simple formulation of the reduced gravity model allows either analytical or straightforward numerical solutions. For simplicity, solutions shown here are obtained through

numerical integration. The model is started from initial states with a fixed amount of warm water in the upper layer and it is forced by a cosine wind stress.

The first case is for a model on the f -plane, i.e., $f = \text{const.}$ is assumed. As shown in upper panels of [Figure 10](#), both the layer thickness and transport of this solution are symmetric with respect to the E–W and N–S directions. The second case is for a model on a beta-plane (i.e., $f = f_0 + \beta(y - y_0)$), and the corresponding solution is asymmetric with respect to the E–W direction, lower panels in [Figure 10](#). In fact, the current near the western boundary is much stronger than in the interior, and this phenomenon is called the western intensification. The dramatic contrast between a model on the f -plane and a model on the beta-plane was first discovered by Stommel in 1948, who recognized the important meaning of such a difference and made a link between this phenomenon and the Gulf Stream and other strong currents observed in the world oceans.

The reason of the western intensification can be explained in terms of the simple reduced gravity model. For the steady flow in the oceanic interior, the lowest order balance of the circulation can be examined in a beta-plane model as follows. Assuming a steady state and omitting the inertial terms and friction terms, the vorticity equation is reduced to Sverdrup relation [eqn \[1\]](#). Thus, the streamfunction satisfies the Sverdrup relation

$$\psi = (\partial \tau^x / \partial y - \partial \tau^y / \partial x)(x_e - x) / \beta \rho_0, \quad [2]$$

and the layer thickness satisfies the following equation

$$h^2 = h_e^2 + \frac{2f^2}{g'\rho_0\beta} \left[\left(\frac{\tau^x}{f} \right)_y - \left(\frac{\tau^y}{f} \right)_x \right] (x_e - x), \quad [3]$$

where h_e is the layer thickness along the eastern boundary, $\beta = df/dy$ is the meridional gradient of the Coriolis parameter.

Figure 10 Layer thickness (a, c) and volume transport (b, d) for a model on an f -plane and a model on β -plane.

The advantage of the reduced gravity model is that it provides a clear description for both the volumetric transport and the depth of the main thermocline. Note that although the quasi-geostrophic theory has been widely used for the description of wind-driven gyres in many previous published textbooks and papers, such a description is inaccurate because the wind-driven circulation involves large deviation of stratification, so that the wind-driven gyration is beyond the validity of the basic assumptions made in the quasi-geostrophic theory.

In a single-moving-layer model for a subtropical basin, the equatorward transport in the basin interior must be closed through the addition of either a western/eastern boundary layer, which can transport the mass poleward. Furthermore, in the Northern hemisphere there is a large amount of negative vorticity input from wind stress over the subtropical basin. In a steady state, the basin-integrated vorticity budget must be balanced; thus, there should be a large source of positive vorticity along the lateral boundaries of the basin.

A simple dynamical analysis indicates that only the western boundary can play the role of generating the positive vorticity and thus balancing the vorticity budget for the wind-driven circulation. The existence of western boundary layer manifests in the form of the so-called western intensification.

Stommel first postulated a boundary layer for a reduced gravity model in terms of bottom friction. He assumed that friction is linearly proportional to the horizontal velocity in the moving layer. In more accurate terminology, his bottom friction can be generalized as the interfacial friction, which is assumed to be linearly proportional to the velocity difference

between the upper and lower layers. Such an interfacial friction can be interpreted as a crude parameterization of baroclinic instability. Another possible type of boundary current is the lateral friction model postulated by Munk. In addition, Charney and Morgan postulated the inertial boundary layer theory.

The structure of western boundary currents postulated in these theories can be examined analytically. Since the western boundary current is rather narrow in the cross-stream direction, the corresponding control equations can be simplified by the standard boundary layer technique. In fact, the cross-stream momentum equation can be simplified in terms of the semi-geostrophic approximation, and simple analytical solutions can be obtained, which can be used to illustrate the essential dynamics of the western boundary current.

All these boundary layer theories can be used to close the wind-driven gyres. A close reexamination reveals that western boundary currents observed in the ocean are primarily controlled by the inertial terms, i.e., these boundary currents are essentially inertial western boundary layer in nature. The frictional force is of importance only within a relatively thin sublayer.

The advantage of the reduced gravity model is that it can predict the basin-wide distribution of the main thermocline depth. The structure of the wind-driven circulation in a closed basin on a beta-plane is shown in the lower panels of Figure 10, where the wind-driven circulation in the subtropical gyre consists of the interior part and the Stommel frictional western boundary current. In this example, the horizontal distribution of the thermocline depth can be seen clearly in

a reduced gravity model, as shown in **Figure 10(c)**. For most part of the basin away from the western boundary the solution is described by the interior dynamics discussed above. On the other hand, the strong northward current appears along the western boundary, i.e., the western intensification.

Layer model with outcropping

An advantage of the reduced gravity model is its capability of capturing the strong nonlinearity associated with horizontal variability of stratification, in particular for the case with isopycnal outcropping. Due to the strong wind forcing, surface heat and freshwater fluxes, isopycnals outcrop at high latitudes. A fundamental assumption made in the quasi-geostrophic theory is that variation of the stratification in the horizontal direction is very small; thus, such theory is not suitable for describing the large-scale dynamics associated with layer outcropping. For a model with finite amount of warm water in the upper layer, in part of the basin the layer thickness becomes thinner and thinner as the wind forcing is enhanced. However, when the continuity equation for the layer thickness is transformed into finite difference forms, using the commonly used central difference scheme, the layer thickness may become negative. In order to avoid such situation, the so-called positive-definite scheme should be used.

A typical solution with outcropping is shown in the upper panels of **Figure 11**, where the upper layer vanishes along the outcrop line near the northwest corner of the basin. North of the outcrop line the lower layer outcrops; within the framework of the single-moving-layer model, there is no motion within the outcrop window. A strong internal boundary current is formed along the edge of the outcrop line, which mimics the

strong western boundary currents after separation, such as the Gulf Stream and Kuroshio. Simulating the case with isopycnal outcropping is a critically important step forward in simulating the wind-driven circulation and the associated density structure in the ocean.

The ventilated thermocline

Although simple reduced gravity models can provide essential information about the wind-driven circulation, such single-moving layer models give no information about the vertical structure of the circulation in the upper ocean.

In pursuing the structure of the wind-driven circulation, the theory of thermocline gradually formed, which is aimed at explaining the three-dimensional structure of the wind-driven circulation. From the beginning of thermocline theory, two paradigms developed independently: the diffusive thermocline by Stommel and Robinson and ideal-fluid thermocline by Welander. The diffusive thermocline theory interprets the main thermocline as an internal thermal boundary layer, and thus emphasizes the critical role of diffusion in forming the main thermocline. On the other hand, the ideal-fluid thermocline theory interprets the main thermocline in terms of ideal-fluid theory, and emphasizes the critical role of adiabatic deformation of the stratification set up by a background thermohaline circulation. Welander actually produced some simple and elegant solutions based on the ideal-fluid thermocline theory.

In the beginning, the theory of diffusive thermocline was pursued by many researchers, apparently due to the seemingly more complete dynamical framework by incorporating the diffusion term. Due to the complicated dynamics involved, exact analytical solutions for the diffusive thermocline were

hard to find. Instead, most studies were aimed at finding different kinds of similarity solutions. The searching for similarity solutions was summed up by Veronis in 1970s. On the other hand, the ideal-fluid thermocline theory was unpopular because it seemed rather incomplete for not including the diffusion terms.

The major deficit of similarity solutions is that they cannot satisfy the essential dynamical constraints, such as the Sverdrup relation; thus, searching for nonsimilarity solutions was a main research frontier. In addition, recent *in-situ* measurements indicate that diffusion in the main thermocline is rather weak; thus, the theory of ideal-fluid thermocline regains its momentum.

One of the conceptual difficulties in pursuing an ideal-fluid theory for the thermocline is as follows. In an ideal-fluid ocean, the interfacial friction must be small and negligible; in such a framework, how are the subsurface layers set in motion? The major breakthroughs took place in early 1980s. Rhines and Young postulated the potential vorticity homogenization theory. They argued that under strong wind forcing, potential vorticity in the subsurface layers is homogenized. As a result, closed potential vorticity contours appear in the subsurface layer, along which water parcels can move freely according to the ideal-fluid thermocline theory. Furthermore, under the assumption of infinitesimal dissipation of potential vorticity, potential vorticity within the close contours are homogenized toward the value along poleward boundary of the circulation. Therefore, a unique solution, which is stable to small perturbations, exists.

Another major breakthrough is the theory of ventilated thermocline. In the stratified ocean, most isopycnals outcrop at high latitudes in winter. The outcropping phenomenon can be clearly seen even in annual mean meridional section of temperature and density, as shown in Figures 5 and 6. Iselin in 1939 first postulated the idea that water masses are formed at

the sea surface in late winter, and subsequently pushed downward through Ekman pumping. His physical insightful idea and Welander's framework of ideal-fluid thermocline were not pursued for a long time. Apparently inspired by the success of the potential vorticity homogenization theory, these two ideas were combined and extended into a beautiful theory of the ventilated thermocline by Luyten, Pedlosky, and Stommel. They formulated the model in terms of three-moving layers plus a deep stagnant layer in the abyss. At lower latitudes, the uppermost layer is exposed to Ekman pumping; however, with the increase of latitudes, upper layers outcrop and lower layers are directly exposed to Ekman pumping. At higher latitudes, Ekman pumping drives the outcropping lower layers in motions, and ventilation and subduction take place.

Ventilation and subduction are the basic elements of the wind-driven circulation in a stratified ocean (Figure 12). The ocean is conceptually separated into four layers; an Ekman layer of the top (not drawn in this sketch), the upper and lower layer below the Ekman layer, and a thick and stagnant layer at the bottom. Wind stress induces the Ekman pumping at the base of the Ekman layer. The upper/lower layer is directly forced when it is exposed to Ekman pumping, as indicated by vertical arrows on the top of the layer. The upper layer outcrops along the zonal outcrop line; thus, north of the outcrop line the lower layer is directly driven by the Ekman pumping. Since the lower layer is exposed to the surface force, we also call this as the ventilation of the lower layer. As a result, there is an anti-cyclonic circulation in this layer, indicated by the blue curved arrows. Poleward of the outcrop line the meridional volume transport in this layer satisfies the Sverdrup constraint.

Equatorward of the outcrop line, the lower layer moves underneath the upper layer, and this is called subduction. Since there is motion in the lower layer north of the outcrop line, there is no reason why it should stop movement after it is subducted; thus, it should continue its anticyclonic movement

Figure 12 Sketch of ventilation and subduction.

after subduction, as indicated by the dashed lines with arrow. South of the outcrop line, the upper layer is directly forced by Ekman pumping. Because both layers are in motion, in this regime the Sverdrup constraint should apply to the meridional volume transport integrated over the total depth of these two layers. In order to determine the solution in this regime, one more dynamical constraint is required. For ideal-fluid motion, the potential vorticity in the second layer should be conserved when it is not directly forced by Ekman pumping. A simple and elegant solution of this problem is postulated in the ventilated thermocline theory. In the ocean interior, relative vorticity is negligible for large-scale motions; thus, potential vorticity for a two-moving layer model is $q_1 = f/h_1$ and $q_2 = f/h_2$. In fact, keeping the potential vorticity of the second layer at its value when it is subducted along the outcrop line gives the additional dynamical constraint for solving the problem.

The theories of potential vorticity homogenization and ventilated thermocline represent major breakthroughs in understanding the three-dimensional structure of wind-driven circulation. In particular, the discovery of shadow zone, the ventilated zone, and the pool zone brought about completely new physical insight for the wind-driven circulation in the upper ocean.

As an example, a two-layer ventilated thermocline model is shown in the lower panels of [Figure 11](#) for a northern hemisphere model ocean, in which the zonal dashed lines indicate the outcropping line of the upper layer. The model is forced by a simple sinusoidal Ekman pumping field, which works on the layer exposed to the upper surface forcing, i.e., the lower layer north of the outcrop line and the upper layer south of the outcrop line. North of the outcrop line, the lower layer is exposed to the Ekman pumping, and an anticyclonic circulation can be clearly seen north of the outcrop line. South of the outcrop line, the lower layer is subducted; however, it continues its south-westward movement as shown in [Figure 11\(d\)](#). The upper layer has zero thickness north of the outcrop line; but, south of the outcrop line it is directly exposed to Ekman pumping.

As shown in [Figure 11\(d\)](#), geostrophic flow in the lower layer after subduction can be separated into three dynamical zones: the pool zone near the western boundary, the shadow zone near the eastern boundary, and the ventilated zone in the middle. An important conceptual breakthrough in the ventilated thermocline theory is the existence of a shadow zone within the subsurface layer near the eastern boundary. A strong kinematic condition along the eastern boundary is the no-flow-penetration condition along the eastern boundary. Thus, the subsurface layer should have a constant thickness h_2 along the eastern boundary. If the eastern boundary were a streamline, then the corresponding potential vorticity f/h_2 should be constant along the eastern boundary. Because the Coriolis parameter declines equatorward, f/h_2 cannot be constant. Therefore, the eastern boundary cannot be a streamline for the subsurface layer; instead, there should be a shadow zone near the eastern boundary where the subsurface layers are stagnant. From hydrographic data, the existence of shadow zone can be inferred from the appearance of extremely low oxygen levels at the depth of 1000 m and near the eastern boundary at low latitudes.

There are two other dynamical zones in [Figure 11\(d\)](#). Potential vorticity in the ventilated zone is sent up along the

outcrop line when the lower layer is subducted. Pool zone is defined by streamlines emerging from the western boundary. As such, potential vorticity in the pool zone is not set up by wind-driven forcing within the basin. Instead, it is set up by either potential vorticity homogenization or other dynamics.

The original Sverdrup relation applies for a single-moving-layer model only. For a model with multiple moving layers, it is extended to an integral constraint for the meridional volume flux for all the moving layers. The ventilated thermocline theory was generalized to a theory for the continuously stratified ocean by Huang. Such a model provides density and current structure in the ocean, which are comparable with observations.

Note that the Sverdrup relation applies for the steady circulation only. There are two important issues related to the application of this relation. First, the steady solution of wind-driven circulation in a basin is established after the wave adjustment. The volume flux over the whole depth of the ocean is established after the barotropic Rossby waves passing through. Since barotropic Rossby waves move quite fast, the timescale for the barotropic circulation to be established is in the order of 7–10 days for a tropical basin.

However, the baroclinic Rossby waves move relatively slowly, with the speed in the order of 0.1 m s^{-1} . Thus, for the midlatitudes of the North Atlantic or the North Pacific Ocean, the steady circulation of the first baroclinic mode takes about 10–20 years to be established. In general, the time-dependent solution of the wind-driven circulation can be calculated by the integrating the time delayed Ekman pumping rate.

Furthermore, the contribution due to eddies is not included in the Sverdrup relation. In the ocean, eddies give rise to nonlinear contribution to the meridional volume flux. As a result, meridional volume flux across the zonal section can deviate from the Sverdrup relation.

Combination of Surface and Deep Currents

Currents in the North Atlantic Ocean

Although surface currents are mostly controlled by wind stress, the thermohaline circulation, which occupies the whole depth of the ocean also manifests in the upper ocean. The circulation in the North Atlantic Ocean is a good example. As shown in [Figure 13](#), there is a warm current crossing the equator. This current moves northward and joins the warm water in the Gulf Stream, which exists as an internal boundary current separating the subtropical gyre to the south and the subpolar gyre to the north. It is important to note that the wind-driven gyre in the North Atlantic Ocean consists of the linear Sverdrup interior and the recirculations. The recirculation regimes are located roughly where the surface expression of the western boundary current emerges from the western boundary region by separation from the coast, where the nonlinearity of the circulation is not negligible. As a result, the Sverdrup dynamics does not apply and eddy activity associated with the nonlinear inertial terms become large and dominating. Instead of the laminar fluid like current, at any given time the Gulf Stream encompasses many large-amplitude eddies.

Furthermore, the total volumetric flux in the Gulf Stream recirculation regime is in the order of 150 Sv, much larger than

Figure 13 Combination of surface wind-driven circulation and deep circulation in the North Atlantic Ocean.

the value predicted from the linear Sverdrup theory. This large volume transport includes contribution of 30–35 Sv due to the linear wind-driven circulation, about 15–20 Sv from the returning flow of the deep thermohaline circulation, and approximately 90–100 Sv due to the nonlinear dynamics (in forms of the southern recirculation and the north recirculation), **Figure 13**. The return flow of the thermohaline circulation continues its poleward movement and appears in the form of the North Atlantic Current, which moves to the high latitude part of the North Atlantic basin and eventually feeds the deepwater formation.

The Antarctic Circumpolar Current

There is a strong circum-earth current system in the South Ocean, and it is called the ACC. There is no meridional boundary in the Southern Ocean. As a result, there is no zonal pressure gradient force to maintain any meridional geostrophic flow; thus, the classical Sverdrup dynamics does not apply to ACC. The formation of ACC depends on many dynamical factors, including wind stress, wind stress curl, the shape of coastline and bottom topography, the surface thermohaline forcing, and, most importantly, the contribution of mesoscale eddies. In particular, mesoscale eddies play capital roles in setting the structure of ACC. ACC plays an important role in regulating the global oceanic circulation and climate. However, the complete description of the ACC dynamics requires an in-depth discussion and it is beyond the scope of this article.

Mesoscale Eddies

Most classical theories of wind-driven circulation treat the circulation in terms of laminar fluids, with the roles of eddies neglected. The framework of three-dimensional structure of gyre-scale wind-driven circulation was completed in 1980s, represented by the multilayer ventilated thermocline theory and its extension to the case of continuously stratified ocean. These theories provided the lowest order structure of the wind-driven circulation and laid down the foundation for the further development of oceanic circulation.

With the advance in technology in observation, theory, and numerical models, the situation has changed rapidly over the

past decade. In fact, physical oceanography is now entering the eddy resolving era. By definition, two kinds of eddies are now the focus of research. The mesoscale eddies have horizontal scales from 10 to 500 km and vertical scales from tens to hundreds of meters, and the submesoscale eddies have horizontal dimensions on the order of 1–10 km and vertical scales on the order of tens of meters or smaller.

The ocean is a turbulent environment, and eddy motions are one of the fundamental aspects of oceanic circulation. In fact, it is estimated that the total amount of eddy kinetic energy is about 100 times larger than that of the mean flow. The roles of mesoscale and submesoscale eddies in the oceanic circulation and climate remain to be explored.

It is expected that with the great technical advances in satellite observation and global observation program like ARGO, eddy study is pushed forward with a great speed. Studies of these eddies, including observations, theory, laboratory experiments, and parameterization in numerical models, will be the most productive research frontiers for the next 10–20 years.

Synopsis

Thermohaline circulation is a major component of the oceanic general circulation. Thermohaline circulation includes water mass formation at the surface, its transportation through the ocean interior, and the return flow to the source region. Thermohaline circulation can have multiple states and catastrophic transitions from one state to the other, and such changes are closely linked to climate changes on the Earth. External mechanical energy is crucial in maintaining the circulation against internal dissipation; thus, mixing parameterization based on external mechanical energy constraint is the key for numerical simulation.

Introduction

What is thermohaline circulation? Literally, thermohaline circulation is the component of oceanic circulation that is directly linked to the density difference induced by temperature and salinity difference. In many previously published textbooks, thermohaline circulation is defined as the circulation driven by density difference induced by surface thermal and haline forcing. According to the new paradigm, thermohaline circulation is a circulation driven by mechanical stirring, which transports mass, heat, freshwater, and other properties in the meridional and zonal directions. Mechanical stirring is supported by external sources of mechanical energy from wind stress and tidal dissipation. In addition, surface heat and freshwater fluxes are necessary for setting up the circulation.

The Cold Deepwater

At low latitudes, surface water is rather warm. The discovery of cold water in the deep ocean at low latitudes by Henry Ellis, captain of Halifax, in 1751 came as a great surprise. Deepwater at low latitudes is much colder than the corresponding lowest temperature at the sea surface in winter; thus, the source of such water mass must be formed at high latitudes where cold water mass can be formed in winter. Tracing cold water formed at high latitudes and its movement to low latitudes led to the theories of thermohaline circulation in the world oceans.

The bottom of the world oceans is covered by cold water originating from a very few narrow sites at high latitudes, where severe winter conditions produce the coldest water in the oceans. Since oxygen solubility is high at low temperature, high oxygen content also indicates the recently formed water mass. Hence, both low temperature and high oxygen concentration can be used as the indication of deepwater formation.

Over the past century, extensive observation data over the world's oceans have been accumulated. Since seawater is slightly compressible, temperature of a water parcel should be slightly increased during a downward adiabatic movement. Hence, the concept of potential temperature is widely used in the description of deep circulation. Potential temperature is defined as the temperature of a water parcel, if it is moved adiabatically (and without changing its salinity) to the sea surface. Potential temperature distribution on the bottom of

the world's oceans is shown in [Figure 1](#). From this figure, the following characteristics of bottom water temperature are readily seen.

Cold water on the bottom is formed around Antarctica, primarily in the Weddell Sea and Ross Sea. The cold water mass formed around the edge of the Antarctic continent that sinks to the bottom of the world oceans is called Antarctic Bottom Water (AABW). From these source regions, bottom water is carried northward and eastward by currents and eddies.

Cold bottom water spreads northward in each basin, mostly in the form of deep western boundary current. Bottom water temperature in the South Atlantic Ocean is the coldest among all basins. In the South Atlantic Ocean, only the Brazil Basin receives AABW directly. Due to topographic setting, the Angola Basin is close to the cold bottom water source from the south. In fact, AABW's effluence to this basin is through a narrow gap near the equator, where relatively cold water moves eastward and finally reaches the Angola Basin from the northern opening passage.

At the northern end of the North Atlantic basin there are different sources of relatively cold water, which originate from the Nordic Seas ([Figure 1](#)). These dense water masses overflow the narrow passages in the Greenland–Scotland Ridge and become the source waters of the deepest component of the North Atlantic Deepwater (NADW).

Over the past century, theories of thermohaline circulation have been developed in order to explain the general circulation related to the formation and spreading of bottom/deepwater and the connection with water in the upper ocean where surface thermohaline forcing prevails. The goal in this article is to explain the physical phenomena and the dynamical theories of the thermohaline circulation in the world oceans.

Water Masses Signature Seen from a Meridional Section

Although thermohaline circulation is often connected to the bottom/deepwater formation and transport, it encompasses many other types of water masses. As an example, the characters of such water masses can be seen clearly from a meridional section ([Figure 2](#)).

From the potential temperature section, the AABW is marked by the low temperature water originated from the edge of Antarctica. The existence of other water masses can be also seen from the salinity section. The AABW is marked by

Figure 1 Potential temperature on the sea floor, based on WOA09 data.

Figure 2 (a) Potential temperature and (b) salinity along 29.5° W, based on WOA09 data.

relatively low salinity. At a shallower level in the southern hemisphere, the Antarctic Intermediate Water (AAIW) marked by a tongue of salinity minimum extends from the surface to the depth of 1 km. Below this tongue of salinity minimum and above the relatively fresh layer of AABW on the bottom is the relatively salty water associated with the NADW, which extends from the North Atlantic Ocean all the way across 40° S and at a depth of 2–3 km. This high salinity tongue is mostly due to the strong evaporation at the surface and sinking of the resulting salty water at middle latitudes in the North Atlantic Ocean.

Surface Buoyancy Forcing

Surface Heat Flux

Surface heat flux is a major forcing for the thermohaline circulation; it is the sum of the four terms: the incoming short-waves solar radiation, the outgoing sensible heat flux, latent heat flux, and long-wave radiation. The net air–sea heat flux map is shown in [Figure 3](#). There is a strong heat flux into the ocean along the equatorial band, in particular the cold tongues in both the Pacific and Atlantic Oceans. Both the Kuroshio and Gulf Stream are the major sites of heat loss to the atmosphere.

Figure 3 Net annual-mean surface heat flux, based on NCEP–NCAR (1979–2010) data.

In addition, the western coast of South America appears as a heat absorption band, which is due to the low sea surface temperature associated with strong coastal upwelling. The high latitude Atlantic Ocean appears as a heat sink, which is related to the strong meridional overturning (Figure 3).

The net heat flux is asymmetric with respect to the equator. In fact, in the Indian Ocean and South Atlantic Ocean, the net heat flux is downward, i.e., the ocean gains heat, instead of losing heat. The net air–sea heat flux distribution implies that there is a meridional heat transport in the ocean; otherwise, the underlying ocean would continuously cool or warm, depending on the sign of the heat flux. In addition, there is a strong zonal transport of heat in the ocean. The zonal heat flux is intimately linked to the oceanic currents, including both the wind-driven circulation and thermohaline circulation.

Surface Freshwater Flux

The surface freshwater flux includes evaporation and precipitation, plus river runoff. Evaporation provides the moisture in atmosphere, and it brings heat from low-latitude ocean to the atmosphere, where water vapor is carried poleward. Water vapor carries a large amount of latent heat, and this is one of the vital mechanisms of poleward heat transport in the climate system. Water vapor in the atmosphere eventually condenses and releases the latent heat content, returning to the oceans or land as precipitation. Freshwater flux through the air–sea interface plays vital roles in regulating the hydrological cycle in the ocean. In particular, freshwater flux is the key ingredient in controlling salinity distribution in the oceans. Hence, freshwater flux is one of the key players in regulating the thermohaline circulation.

Strong evaporation appears in the subtropics and the western boundary current system in both hemispheres. In particular, both the Gulf Stream and Kuroshio System are the

regions with the maximal evaporation rate in the global oceans. The oceans receive the returning water as precipitation from the atmosphere, plus river runoff. The major regions of strong precipitation include the equatorial Pacific Ocean and the South Pacific Convergence Zone, which extends southeastward in the South Pacific Ocean, with the annual-mean precipitation rate of more than 4 m per year. In addition, there are large regions of strong precipitation in the equatorial Indian Ocean and Atlantic Ocean (Figure 4).

The difference in evaporation and precipitation is what really affects the haline circulation in the oceans. The pattern of the net freshwater flux across the air–sea interface is dominated by two features: the strong precipitation bands and the strong and relatively narrow regions of strong evaporation. Overall, the equatorial band is dominated by a net gain of freshwater. In particular, there is strong net freshwater flux, on the order of 3 m per year, into the western equatorial Pacific Ocean and the eastern equatorial Indian Ocean. On the other hand, the eastern parts of the five subtropical basins in both hemispheres appear as deserts in the oceans, where the annual-mean net freshwater loss to the atmosphere is on the order of 1–1.5 m per year.

Surface Buoyancy Flux

Surface thermohaline forcing is often converted into the density flux, which is defined as

$$F_\rho = -\rho_0(\alpha F_T - \beta F_S)$$

where $\alpha = -\frac{1}{\rho_0} \frac{\partial \rho}{\partial T} \Big|_{P,S}$, $\beta = \frac{1}{\rho_0} \frac{\partial \rho}{\partial S} \Big|_{P,T}$ are the thermal expansion coefficient and saline contraction coefficient, ρ is seawater density, ρ_0 is the constant reference density; $F_T = Q/\rho_0 c_p$, Q is the net heat flux into the ocean, c_p is the heat capacity of water; $F_S = (E - P)S/(1 - 0.001S)$, $E - P$ is evaporation minus precipitation, S is sea surface salinity in unit of part per thousand.

Figure 4 Annual-mean evaporation minus precipitation, based on NCEP–NCAR data.

Density flux is primarily controlled by the net air–sea heat flux; thus, its distribution shares features similar to the net air–sea heat flux, with opposite signs. Near the equator, the density flux is negative, indicating that surface heating reduces water density; this is true especially in the cold tongue of the eastern equatorial Pacific Ocean. In both the Gulf Stream and Kuroshio, density flux is positive, reflecting the strong air–sea heat loss to the atmosphere.

Overall, density flux over the most part of the North Atlantic Ocean is positive, but it is negative in the northern North Pacific Ocean (Figure 5). This difference reflects the fact that North Atlantic Ocean is much warmer than the North Pacific Ocean. As a result, there is strong evaporation in the North Atlantic Ocean, even at high latitudes. Such a difference is primarily due to the existence of a strong thermohaline overturning circulation in the Atlantic Ocean. The regions of positive density flux are closely linked to the site of water mass formation, including mode water formation and deepwater formation. This map does not include the contribution associated with sea-ice formation; thus, the site of bottom water formation in the Weddell Sea cannot be clearly identified from this map.

Water Mass Formation

Bottom Water Formation

Under the current climate condition, bottom water is formed in the Weddell Sea, labeled as number 6 station in Figure 6. Due to the cold and dry air from the Antarctic continent, sea ice is formed along the edge of the continent, in particular in the Weddell gyre. Salt rejection during the sea-ice formation

increases the salinity of the underlying water parcels. This heavier water mass flows down the Antarctic continental slope, mixing with the ambient water on its way.

There are many other sites in the world’s oceans where dense water masses are formed through local air–sea interaction. Although some of these water masses may have density higher than the source water from the Weddell Sea, they cannot sink to the bottom of the world oceans. This is due to a very special thermodynamic property of seawater, the so-called thermobaricity. The most important point in connection with the thermobaricity is that the cold and relatively freshwater is more compressible than the warm and relatively saline water. Assume that there are two water masses with the same density at the sea surface, except that one is warm and salty and the other is cold and fresher. Because of thermobaricity, the first water parcel can be heavier than the second one at greater depth.

The source water from the Weddell Sea is cold and relatively fresh. Due to the difference in compressibility, it can be further compressed and thus form the densest water in the bottom of the world oceans. On the other hand, although the NADW and other types of water masses formed at the sea surface may be heavier at the sea surface, they are less compressible, and, as such, cannot sink to the bottom of the world oceans.

Deepwater Formation

Under the current climate condition, the most prominent type of deepwater in the oceans of the world is the NADW. There are two different ways of this deepwater formation. In Type 1, deepwater can be formed in the open ocean, typically in the

Figure 5 Annual-mean density flux at the sea surface, based on NCEP–NCAR data.

Figure 6 Deep/bottom water formation in the Atlantic sector and the related currents. Heavy blue curve and circles indicate sites of bottom/deep-water formation; heavy green circle and curve indicate Mediterranean water formation and its pathway; red curves with arrows depict warm surface currents; light blue curves with arrows indicate deep boundary currents.

center of a cyclonic gyre, where the stratification is weak. In late winter, strong surface cooling can induce chimneylike density structures in the middle of the gyre, where dense water is formed and sinks to a deeper part of the water column. In Type 2, water advected by oceanic currents can gradually increase in density due to cooling and salt rejection along the path of the current. The dense water so formed along the path of the currents sinks to depth and thus constitutes the source of deepwater.

NADW formed under the current climate conditions can be further separated into an intermediate and deep component. The intense air–sea forcing in the Nordic Seas, together with the oceanic preconditioning, provides a suitable environment for the origin of the deep component. Both Type 1 and Type 2 formations occur here. In particular, the inflowing subtropical-origin Atlantic water is densified as it circumnavigates the Nordic Seas within the boundary current system (Type 2 formation, denoted by the heavy blue curve in [Figure 6](#)), ultimately exiting Denmark Strait in the East Greenland Current (light blue solid curve in [Figure 6](#)). In addition, open-ocean convection occurs in the Greenland and Iceland Seas (Type 1 formation), which is believed to supply dense water to both the Faroe Bank and Denmark Strait overflows. A newly discovered current, the North Icelandic Jet, carries the transformed water from the Iceland Sea into Denmark Strait (depicted by number 2 station in [Figure 6](#) and the light blue line that emanates from it).

The intermediate component of NADW has two primary sources. On the east side of the southern tip of Greenland, the steep topography of the coast leads to strong local winds. This, in conjunction with cold wintertime air temperatures, drives middepth convection and water mass formation (labeled by the number 3 station in [Figure 6](#)). In addition, wintertime cooling in the western Labrador Sea leads to the formation of Labrador Sea Water, which is believed to be the major source of the intermediate component of NADW (number 4 station in [Figure 6](#)).

NADW is advected southward by the deep western boundary current in the North Atlantic and eventually reaches the southern hemisphere, as depicted by the slight blue curves with arrows in [Figure 6](#).

An additional source of deepwater formation is in the Mediterranean Sea, where wintertime convection creates a water mass known as Mediterranean water (MW, labeled station 5 in [Figure 6](#)). MW overflows the Strait of Gibraltar into the eastern North Atlantic Ocean. Due to the high salinity at the sea surface, MW is heavier than the source waters of the AABW and NADW. However, because it is warm and salty, MW is less compressible than these deep/bottom water sources. As a result, MW cannot sink to the bottom of the world oceans; instead, it equilibrates near a depth of 1000–1500 m in the North Atlantic Ocean (depicted by the green curve with arrows in [Figure 6](#)).

Mode Water Formation

Thermohaline circulation is a technical term, which should include many types of circulation related to density difference induced by thermohaline forcing; thus, it includes many different types of water mass formation. In addition to

the bottom and deepwater masses formation discussed above, there are other types of water masses formed at much shallow depth. Water mass formation is distributed non-uniformly in the temperature–salinity space. In fact, much of water mass formation is concentrated around some rather narrow regions in the space of temperature and salinity. In general, these water masses are formed and circulated at relatively shallow depth, and they are often called mode water, such as Subtropical Mode Water, Subpolar Mode Water, and AAIW.

Mode water formation takes place primarily at the air–sea interface. This process is often called subduction – which takes place in later winter at the base of the mixed layer. This is a combination of downward pumping due to the wind-driven circulation in the upper ocean and the thermohaline process in the upper ocean. After its formation, mode water is carried out by the three-dimensional thermohaline circulation, modifying its properties on the path gradually through turbulent and eddy mixing. Mode water eventually loses its identity through obduction, which is a process opposite to subduction. Mode water formation and its variability are closely related to the climate condition, in particular the air–sea interface exchanges of heat and freshwater flux.

The typical depth range of mode water circulation is within the top kilometers of the ocean. As a result, mode water formation, including their site and annual rate, is closely linked to climate change on interannual and decadal timescales.

The major features of the meridional circulation in the Atlantic Ocean are shown in [Figure 7](#). Note that circulation in the ocean is truly three-dimensional in nature. Therefore, when reading such a sketch, one should not forget that there are many other important components of circulation excluded from the sketch. Most importantly, wind-driven gyres primarily appear in the form of horizontal gyration, which is excluded from such a meridional sketch.

The most important components of the thermohaline circulation in the Atlantic section include two cells. First, there is a deep cell related to the AABW. Water associated with this cell originates from the edge of Antarctic and moves northward along the bottom of the ocean, crossing the equator and moving all the way to the lower latitudes in the North Atlantic Ocean. Along this path, it is gradually mixed with the relatively light water of NADW through diapycnal mixing driven by tides and internal waves.

Second, a slightly shallower overturning cell is linked to NADW. This cell starts from high latitudes in the North Atlantic Ocean. Because the NADW is lighter than the AABW, it cannot sink to the sea floor; instead, it sinks to the depth range of 4 km and spreads southward. NADW and AABW encounter each other mostly in the southern hemisphere. The strong westerlies in the southern hemisphere drive the strongest upwelling system in the world oceans. Through this upwelling system the NADW is moved upward all the way to the sea surface, including its water mass properties modified by diapycnal mixing along its pathway.

On much shallow levels, the thermohaline circulation appears in the form of mode water ventilation and subduction and the subsequent meridional overturning circulation, as depicted by red and pink color arrows in [Figure 7](#).

Figure 7 Sketch of water mass formation and meridional overturning cells in the Atlantic Ocean.

Theory of Deep Circulation

After bottom and deepwaters are formed in the source regions, they move through the world's oceans in the form of deep circulation. In general, there are three key components of the deep circulation.

First, most sources of bottom/deepwater mass are formed in marginal seas, which are separated from the open ocean by narrow channels. As these source waters flow through the narrow channels, they overflow some relatively shallow ridges. When deepwater overflows shallow ridge, the current speed can exceed the corresponding signal speed of internal gravity waves. Thus, a phenomenon called the internal hydraulic jump takes place, which is also called deepwater fall. The volumetric flux of such deepwater fall can be quite large, on the order of a few Sv ($1 \text{ Sv} = 10^6 \text{ m}^3 \text{ s}^{-1}$), and the corresponding elevation drop of a few hundred meters. In comparison, the water falls on land are much smaller. For example, the well-known Niagara Falls has a volumetric flux of $3000 \text{ m}^3 \text{ s}^{-1}$, and the corresponding elevation drop is about 56 m.

After leaving the source region, bottom/deepwater circulates the world oceans. The basic theory of deep circulation was postulated by Stommel and Arons in a series of semi-narian papers published in the 1960s. They assumed that the ocean had a flat bottom with no topography and there was a uniform upwelling in the basin interior. For a model on a beta-plane and in a steady state, the linear vorticity equation predicts that water from the source region must flow through the world oceans in the form of deep western boundary currents. On the other hand, in the basin interior the linear potential vorticity balance requires that there is a universal poleward flow.

Their theoretical prediction of the existence of deep western boundary currents was quickly confirmed by field observations, and this was called one of the most remarkable advances in dynamical oceanography. Over the past half century, many deep boundary currents were discovered through well-planned

hydrographic surveys in the world oceans. The existence of deep boundary currents was considered as a solid proof of the theory. On the other hand, the poleward flow in the oceanic interior predicted by the theory has not been tested through observations, and this is due to the fact that the poleward velocity predicted by the theory is so small that it was rather difficult to measure.

Stommel and Arons theory of deep circulation dominated the study of deep circulation for more than 30 years. With the great advance in the ocean measurement technique, theory, and numerical models, their theory was reexamined. The conclusions of their theory are a simple logic consequence of the basic assumptions. However, there is no reason a priori, why the upwelling in the ocean interior should be uniform. There are steep bottom topographic features and the circulation is not necessary in a steady state.

Recent studies based on *in-situ* observations and numerical simulations with high resolution reveal the following issues. There are indeed deep western boundary currents as predicted by the Stommel and Arons theory; however, due to eddies and topographic features, such boundary currents can be different from the simple laminar boundary current predicted by their theory. In the ocean interior, instead of the universal poleward flow, the deep basin can be occupied by zonal alternative deep jets with strong eddies. In simple words, the deep circulation is much more complicated and rich in dynamical features than the simple deep circulation pattern predicted by the Stommel and Arons theory.

Freshwater and Haline Circulation

Although the role of thermal forcing is quite familiar for most people, the role of freshwater forcing and the haline circulation are rather unfamiliar. Freshwater flux through the air-sea interface appears in the form of evaporation and precipitation, plus the river runoff. In addition, salt rejection during sea-ice

formation and freshwater resulting from ice melting are also important sources of freshwater flux in the upper ocean.

Evaporation and precipitation often appear as intermittent processes, but the thermohaline circulation in the oceans is much more persistent; thus, the idea that such infrequent freshwater flux can be linked to the thermohaline circulation seems nonintuitive. However, thermohaline process has a timescale much longer than the typical timescale of the intermittence related to surface evaporation and precipitation. Consequently, over the much longer timescale, the effect of surface evaporation and precipitation appears as well organized surface forcing.

In fact, Hough in 1897 made the first attempt of theorizing the oceanic current. In a study of tidal circulation, he postulated a simple model for the evaporation- and precipitation-driven flow on a sphere. His model is rather simple and does not take friction into consideration. In 1933, Goldsbrough made a great improvement in the freshwater-driven circulation. To find a closed solution driven by freshwater flux he assumed a rather special evaporation and precipitation pattern, in which the net evaporation and precipitation is zero along any fixed latitude of a basin. His solution was further improved by Stommel, who postulated to close the freshwater-driven circulation by adding the western boundary current. Thereby, the circulation driven by freshwater flux is often called the Goldsbrough–Stommel solution.

Although Goldsbrough and Stommel laid the foundation of the freshwater-driven circulation, their theory was mostly neglected over a long time. The primary reason of such situation is due to the fact that the strength of the circulation driven by freshwater flux alone is on the order 1 Sv, which is at least one order of magnitude smaller than the circulation observed in the oceans.

A close reexamination reveals the reason of such a problem. The seawater is loaded with salt, and there is strong mixing of salt (or freshwater) in the oceans. Goldsbrough–Stommel theory was formed for the freshwater only without considering the role of salt and mixing. If the ocean has no salt, or if there is no mixing of salt in the ocean, the only circulation driven by surface freshwater flux should be that predicted by the Goldsbrough–Stommel theory. In reality, due to strong mixing in the ocean the freshwater induced circulation has two components: a barotropic component as predicted by the Goldsbrough and Stommel and a baroclinic component which is at least one order of magnitude stronger than the barotropic component.

Therefore, for the thermohaline circulation the air–sea interface freshwater flux plays roles as important as the surface heat flux. From a more general point of view, freshwater flux through the air–sea interface is part of the hydrological cycle in the climate system. Hydrological cycle can appear in quite different forms, such as moisture and clouds in the atmosphere, precipitation and evaporation through the air–sea interface, and water transported through the oceans.

Among many roles played by the hydrological cycle, poleward heat transport is a key component of the climate machinery. Poleward heat flux in the climate system is carried out by the general circulation in the atmosphere and oceans. Traditionally, poleward heat flux is separated into two parts. In the atmosphere, the poleward heat flux consists of the heat flux

carried by the dry atmosphere and the heat flux carried out by the moisture. The rest of the poleward heat flux is carried out by the oceanic general circulation.

However, the moisture circulation in the climate system is essentially an atmosphere–ocean coupled mode. At low and mid-latitudes, moisture is carried by the atmospheric circulation to high latitudes, where it is transformed by precipitation (rain and snow) and enters into the oceans. The equatorward return flow of the global hydrological cycle is mostly through the oceanic currents, or the meridional overturning circulation in the ocean. It is clear that without the oceanic thermohaline circulation the moisture transport in the atmosphere would be incomplete. Thus, one can also separate the poleward heat flux into three components: the sensible heat flux carried by the dry atmosphere, the sensible heat flux carried by the oceanic current, plus a third component carried by the moisture transport in the atmosphere and the return haline circulation in the oceans. Comparing with the traditional way of classifying the poleward heat flux, this three-component view may provide more accurate description of the relevant physics.

Sandstrom Theorem and Framework for Thermohaline Circulation

Sandstrom Theorem

Atmospheric general circulation can be interpreted as a heat engine, and the great success in atmospheric science led people to believe that the equator–pole temperature difference in the ocean can drive a strong thermohaline circulation. In fact, the theory of thermohaline circulation discussed in many previous publications were based on the idea that ocean is a heat engine.

Starting from late the 1990s, people began to realize that thermohaline circulation may work in a way fundamentally different from the general circulation in the atmosphere. In fact, more than 100 years ago, Sandstrom postulated a framework for thermally forced circulation in the environment of gravitational field. He argued that the thermally forced circulation of a system can be idealized as a Carnot cycle (Figure 8). When the system is heated from above and cooled from below, no mechanical energy can be generated from the cycle. As such, the system cannot be self-sustained against the friction, so there is no circulation. On the other hand, if the system is heated from below and cooled from above, net mechanical energy can be generated through each cycle. Thus, system can be self-sustained against the internal friction. Sandstrom also carried out laboratory experiments and found that when the heating source was below the cooling source, there was strong circulation; however, when the heating source was above the cooling source, there was no circulation.

The atmosphere receives the solar radiation, which is primarily absorbed by the ocean and land at the lower boundary first and then reflected back, i.e., it is a system heated from below. The outer space works as the cooling source at the upper boundary; hence, the atmosphere is cooled from above. According to Sandstrom theorem, the atmosphere is a heat engine.

The ocean is mostly heated and cooled from the upper surface. Due to thermal expansion, sea level at low latitudes, where heating takes place, is about 1 m higher than the sea level

Figure 8 Two settings of thermal engine illustrating the Sandstrom theorem. (a) When heating is above cooling the circulation cannot be self-sustained. (b) When heating is below cooling the circulation can be self-sustained.

at high latitudes where cooling takes place. Cooling and heating from the same geopotential level is called horizontal differential heating. The behavior of a system under horizontal differential heating is currently a research frontier.

According to the Sandstrom theorem, there should be no convectively driven circulation in the ocean. There is, however, strong overturning circulation in the world's oceans, which seems in contradiction to the Sandstrom theorem. According to the new theoretical framework, the existence of strong overturning circulation in the ocean can be explained as a circulation driven by external source of mechanical energy.

School of Pushing and School of Pulling

The framework of thermohaline circulation can be classified into different schools.

School of pushing

Deepwater formation pushes deep currents and thus drives the thermohaline circulation.

This is the classical school for the thermohaline circulation, in which thermohaline circulation is thought to be driven by surface thermohaline forcing, in particular the surface cooling/heating. Surface cooling produces dense water that sinks to a great depth. The high latitude ocean is filled up with cold and dense water from surface to bottom. Combining with the warm and light water in the upper ocean at low latitudes, this creates a pressure force in the abyssal ocean, driving cold bottom water toward low latitudes and thus pushing the meridional circulation (Figure 9(a)). This school is based on the connection between meridional overturning circulation and pressure difference induced by surface thermohaline forcing and deep-water formation.

For example, in a two-box model Stommel assumes that the circulation rate is proportional to the north-south pressure difference. Furthermore, the proportional constant relating to the pressure difference and overturning rate is assumed to be invariant under different climate conditions.

The school of pushing views the thermohaline circulation as buoyancy controlled. Many people believe that the strong circulation induced by sudden cooling may well be a strong

support for this theory. However, a close examination reveals that the strong circulation after the onset of sudden cooling is due to the release of a large amount of gravitational potential energy during the convective adjustment. In fact, the total amount of mechanical energy for the mean state is greatly reduced during such sudden cooling. Furthermore, the circulation would decline gradually, if there were no continuous supply of external source of mechanical energy.

School of pulling

Pulling by deep mixing

Deep mixing removes cold water from the abyss and maintains the stratification and circulation.

The major problem of the school of pushing is as follows. If there were no external source of mechanical energy to sustain mixing, cold water would pile up in the ocean; as a result, the solution is eventually reduced to a very weak circulation. To maintain a sizable circulation, the cold water in the abyss should be removed. Deep mixing sustained by tidal mixing can transform cold water into warm water in the deep ocean, creating room for newly formed deepwater and thus pulling the thermohaline circulation.

Pulling by wind stress

The Southern westerlies pull cold water from the deep ocean and thus maintains the global thermohaline circulation.

Under the current topographic and climate setting, a strong Ekman upwelling around the latitude band of 50–60° S exists, which is closely related to the Antarctic Circumpolar Current. Due to this strong upwelling, NADW is pulled up to the upper ocean. In the upper ocean, wind stress continues to input mechanical energy through Ekman layer and surface waves, and water properties are gradually modified in the surface mixed layer on the way northward.

These two ways of pulling can work together as follows. Wind-driven upwelling and mixing in the upper ocean can build up the major parts of the thermohaline circulation and water mass transformation in the world's oceans, while the remaining parts of the water mass transformation in them are relatively small and can be accomplished by external mechanical energy from tidal mixing (Figure 9(b)).

Figure 9 Two schools of the thermohaline circulation in the world oceans. (a) Pushing by deepwater formation. (b) Pulling by deep mixing and wind stress.

Three Paradigms

Thermohaline circulation in the ocean is a very complex system; thus, it can be studied from quite different angles.

Buoyancy paradigm

Thermohaline circulation is driven by horizontal buoyancy difference or deepwater formation; thus, energetically the ocean is driven by surface thermohaline forcing. The oceans receive huge amount of thermal energy in the form of short-wave radiation (60.8 PW, $1 \text{ PW} = 10^{15} \text{ W}$), and sending back heat flux in forms of latent heat (35 PW), long wave radiation (21.2), and sensible heat (4.7 PW), **Figure 10(a)**.

In simple box models the circulation rate is assumed to be linearly proportional to the north-south density difference. In many oceanic general circulation models and other numerical models used in climate study, the diapycnal diffusivity is treated as a fixed parameter of the model. The common practice in choosing such parameter is by tuning the model to reproduce an overturning rate that matches the present-day observations.

The salient points of this paradigm are: the diffusivity is considered as fixed parameters intrinsic to the model. The same diffusivity is used in the model to simulate circulation under different climate conditions, such as the circulation during the last glacial maximum or circulation under the global warming scenario for the next 100 years.

Mechanical energy paradigm

Buoyancy forcing in the upper surface cannot generate mechanical energy required to overcome friction/dissipation associated with circulation. In order to maintain the circulation against friction/dissipation, external sources of mechanical energy are needed. The major external sources of mechanical energy sustaining the oceanic circulation include wind stress energy (64 TW) and tidal dissipation (3.5 TW) (**Figure 10(a)**). Accordingly, the thermohaline circulation is a mechanical conveyor transporting mass, heat, and freshwater fluxes, and it is directly driven by the external source of mechanical energy. Diapycnal mixing is subject to the mechanical energy constraint.

Since the sources of mechanical energy change with the atmospheric wind conditions and tidal dissipation, diapycnal diffusivity should change with climate and tides. However, the circulation rate is not necessarily linearly proportional to the amount of mechanical energy sustaining the circulation. It is important to emphasize that the mechanical energy paradigm is relatively young, and the relevant theories and parameterization will take a long time and much effort to be developed. With recent interest in this new paradigm, it will become more mature and competent in the near future.

Entropy paradigm

Entropy balance is one of the fundamental thermodynamic laws governing the universe, including the oceanic circulation. In a quasi-steady state, the total amount of energy fluxes

Figure 10 Energy and entropy fluxes in the world oceans. (a) Energy fluxes in the world oceans (in 10^{15} W). (b) Entropy fluxes in the world oceans (in 10^{12} W K^{-1}). (Question marks indicate highly uncertain value.) Updated from Huang, R.X., 2010. *Ocean Circulation, Wind-Driven and Thermohaline Processes*. Cambridge Press.

entering and leaving the system should be equal (Figure 10(a)). The balance of entropy flux is totally different. The oceanic circulation is a dissipated system, so that it generates entropy internally. As a result, the circulation is associated with the negative entropy fluxes. Thus, entropy is not conserved, i.e., the entropy flux carried by short-wave radiation into the system ($H_{sw} = 14 \times 10^{12} \text{ W K}^{-1}$) is smaller than the entropy flux leaving the system ($H_{lh} = 120 \times 10^{12} \text{ W K}^{-1}$ for latent heat; $H_{lw} = 97 \times 10^{12} \text{ W K}^{-1}$ for long wave radiation; $H_{sh} = 16 \times 10^{12} \text{ W K}^{-1}$ for sensible heat) (Figure 10(b)). The removal of entropy is implicitly part of the air-sea heat exchange, including the incoming short-wave solar radiation of low entropy and the high entropy fluxes associated with outgoing heat fluxes. This net entropy flux plays a vitally important role in maintaining the ocean circulation against the accumulation of entropy associated with heat/salt diffusion in the ocean.

There are additional sources of entropy. Heat transported from regions of high temperature to regions of low temperature is one of the important sources of internal entropy production. The poleward heat transport is in the order of 1.5–2 PW. The entropy production due to oceanic heat transport is estimated as $6.8 \times 10^{12} \text{ W K}^{-1}$. The rate of entropy production due to freshwater mixing in the oceans is $0.11 \times 10^{12} \text{ W K}^{-1}$. These estimates may serve as the theoretical lower bound of entropy production due to heat transport and hydrological processes in the world's oceans; a detailed balance and its geographic distribution of these terms remain unclear.

According to the new paradigm of thermohaline circulation, mechanical energy involved in thermohaline circulation comes from the external sources of wind/tides. Thus, the total mechanical energy dissipation rate is equal to the rate of input from the external sources of mechanical energy. As a result, for the world's oceans the total entropy production due to momentum dissipation in the world oceans is estimated at $H_{diss} = 0.24 \text{ TW K}^{-1}$. However, most of this energy is dissipated in the surface mixed layer and shallow seas. The total amount of external mechanical energy sustaining the turbulent mixing in the subsurface ocean interior is in the order of 1 TW. Hence, the entropy production associated with mechanical energy dissipation, which in turn is associated with mixing in the ocean interior, is on the order of 0.004 TW K^{-1} .

Mechanical Energy and the World Ocean Circulation

Mechanical Energy Balance

As discussed above, although there is a large amount of thermal energy going through the ocean, it cannot be efficiently converted into mechanical energy sustaining the oceanic circulation against the dissipation. On the other hand, although mechanical energy from external sources is 1000 times smaller than the thermal energy flux, it can be used to compensate the dissipation associated with oceanic circulation. Thus, in terms of maintaining the oceanic circulation against dissipation, external sources of mechanical energy is the real force driving the oceanic circulation. In this sense, surface thermohaline forcing works as the necessary preconditions for the thermohaline circulation.

Two of the most important items are the tidal contribution and the wind stress energy input to the surface geostrophic

currents. Munk and Wunsch gave the first rough estimate of tidal dissipation based on tidal assimilation with altimetry data. The net dissipation rate of the surface tides is 3.5 TW ($1 \text{ TW} = 10^{12} \text{ W}$). Most of tidal dissipation takes place in the marginal seas, and there is roughly 0.9 TW left for the tidal dissipation in the open oceans. Tidal dissipation is primarily through internal wave breaking and converting into small-scale turbulence. In a stratified flow, vertical mixing pushes light fluid downward and dense fluid upward; thus, it can convert turbulent kinetic energy into the potential energy of the mean state. The efficiency of such conversion is low, in the order of 0.15–0.2. Therefore, the gravitational potential energy generated by tidal mixing in the open ocean is approximately 0.18 TW.

The other important item is wind stress input to the surface geostrophic current, which is estimated at 0.9 TW. The pathway of this energy remains unclear at this time. Surface wind also contributes mechanical energy into the Ekman layer (3.1 TW) and a huge amount of energy into the surface waves (in the order of 60 TW). However, most of such energy is dissipated within the surface wave boundary layer and the frictional Ekman layer; how much of the mechanical energy from surface wind can penetrate through the base of the mixed layer remains unclear till now.

In summary, our knowledge of mechanical energy balance in the world's ocean remains preliminary. Due to the complicated nature of the relevant physics, we do not yet know how many items are on the list. In a sense, the energy diagram shown in Figure 11 should be taken as a rough estimate only. In fact, many values cited in this diagram are no better than within a factor of two.

What Controls the Strength of the Meridional Overturning Cells?

Simple scaling analysis suggests that under the assumption of constant meridional density difference, the strength of the meridional overturning circulation is proportional to one-third power of the vertical eddy diffusivity. In a stably stratified ocean, vertical (or more accurately, diapycnal) mixing pushes light water downward and heavy water upward; thus, it requires external source of mechanical energy.

Most oceanic general circulation models were run under the assumption that vertical eddy diffusivity was a model parameter, which the modeler could tune more or less arbitrarily, 20 years ago. As the theory of thermohaline circulation advanced over the last two decades, it is now commonly accepted that external sources of mechanical energy from tides and winds must be used as the integral constraint for parameterizing eddy diffusion.

Climate changes can affect the thermohaline circulation in different ways. First, climate changes can alternate the surface thermohaline forcing, such as the air-sea surface heat flux and freshwater flux. Because of such changes in the surface boundary conditions, the thermohaline circulation can be alternated in response. For example, surface freshening may induce thermohaline catastrophe and surface cooling may induce a rapid enhancement of thermohaline overturning circulation. However, in order to maintain a steady state of circulation, the external mechanical energy sustaining the circulation is required.

Figure 11 Mechanical energy diagram for the world oceans. (Question marks indicate uncertain values.)

Second, the external mechanical energy from tides and winds can also change with climate. With changes in the external sources of mechanical energy, the thermohaline circulation must be changed in response, because the energy sustaining the circulation against friction is alternated.

Multiple States and Thermohaline Catastrophe

Multiple States

Thermohaline circulation can be studied using simple box models. In 1961, Stommel idealized thermohaline circulation in terms of a two-box model, in which the low-latitude ocean is represented by a single box and the high latitude ocean is represented by another box. These two boxes are linked by imaginary pipes and subject to relaxation conditions for both temperature and salinity. Stommel assumed that relaxation time for salinity was much longer than that of temperature.

This seemingly oversimplified model provides much of the dynamical structure essential for thermohaline circulation in the world's oceans. Introducing two new variables $T = T_1 - T_2$ and $S = S_1 - S_2$, the problem is reduced to solving a simple set of ordinary differential equations of two unknown variables; the solution of this problem can be found in the traditional T - S diagram used in oceanography.

Most importantly, the model has three steady states, as shown in Figure 12. There is a stable thermal mode, which is characterized by sinking of cold and relatively freshwater at the high-latitude box; this is compensated by the equatorward return flow and upwelling at the low-latitude box. The thermal mode is characterized by a relatively fast overturning rate. There is a stable haline mode, which is characterized by sinking of the relatively warm and salty water at the low-latitude box. There is

a compensated flow through upwelling at the high-latitude box. The haline mode is characterized by a relatively slow overturning rate. In addition, there is an unstable thermal mode. Although Stommel's model seems oversimplified, it captures the essential dynamics of the thermohaline circulation, such as the multiple solutions, and these dynamical features have been reproduced in many much more complicated models.

Stommel's box model was designed for a single hemisphere ocean, and it was extended into a three-box model for a two-hemisphere ocean by Rooth. In the two-hemisphere ocean, there are pole-pole modes in which circulation can be primarily controlled by temperature-induced density difference or salinity-controlled density difference. In fact, the modes symmetric with respect to the equator are unstable, and tend to drift toward the pole-pole modes.

Thermohaline Catastrophe

The multiple steady states of thermohaline circulation can be unstable, and catastrophic transition from one steady state to another steady state can take place. Using a numerical oceanic general circulation, F. Bryan discovered the catastrophic transitions from a steady symmetric solution in a two-hemisphere ocean model to a steady asymmetrical solution. Since thermohaline circulation can carry a substantial amount of thermal energy and transport it to high latitudes, the catastrophic transitions of the thermohaline circulation can bring about abrupt changes in the climate condition in the Earth. In particular, such abrupt transitions can be tricked by adding a freshwater cap at the deepwater formation site at high latitudes. Due to its close connection with the freshwater cap, such catastrophic transitions are often called the halocline catastrophe.

Figure 12 Stommel's two-box model.

Thermohaline circulation plays a critical role of transporting heat poleward, which is a substantial component of the climate system. Past climate proxies indicated that climate system went through many abrupt changes over the past. Therefore, the multiple states and catastrophic changes of thermohaline circulation have capital implication for climate change. For example, Nanabe and Stouffer found that the atmosphere-ocean coupled system can have two steady states, one corresponding to the current climate setting and the other to a state, in which the North Atlantic Ocean is much colder and fresher. The maximum temperature and salinity differences are 5°C and 3‰ .

Thermohaline circulation can have multiple states and oscillations over a broad range of spatial and temporal scales. For example, thermohaline circulation component in connection with the freshwater flux can oscillate in decadal timescale. Furthermore, thermohaline circulation can oscillate on the timescale of thousands of year, a phenomenon called flushing. These types of oscillation are closely linked to the three models discussed above, namely Stommel's two-box model, F. Bryan's two-hemispheric numerical model, and the Manabe-Stouffer coupled model. These models materialized different degrees of idealization for the climate system. However, the multiple stable equilibrium states obtained from these models share fundamentally similar structure. Paleoclimatic records indicate that the meridional circulation in the Atlantic basin has gone through On/Off cycles; thus, one of the most important frontiers in oceanic circulation and climate study is whether such an abrupt change in the North Atlantic circulation may happen in the near future. In particular, the main focus is the potential impact of changes of hydrological cycle and freshwater flux in the climate system.

A likely scenario of global warming is the intensification of hydrological cycle. With more evaporation at low latitudes and more precipitation at high latitudes, the meridional salinity gradient can be enhanced, producing a meridional pressure difference against that due to thermal forcing. As a result, the meridional overturning cell associated with the NADW may be slowed down and even be interrupted. Accordingly, many of

the state-of-art climate models predict that meridional overturning circulation in the Atlantic basin will be substantially reduced over the next hundred years.

In view of global climate changes, within the next 30–50 years the Arctic Ocean may be ice free in summer time. Without the ice, the large amount of relatively freshwater in the Arctic Ocean could be carried out to the North Atlantic Ocean, where such large amount of freshwater may intricate a halocline catastrophe, similar to what has been simulated by F. Bryan and others.

Although climate models have been improved greatly over the past, these models need to be further improved. In particular, the oceanic component of most current climate models is based on the old theoretical assumption that vertical diffusivity is invariant under different climate conditions. In the point of view of the new energy theory, wind stress, and to a lesser degree, the tidal dissipation can be quite different under different climate conditions. Thus, results from such model experiments remain questionable. It is expected that with the rapid progress toward unraveling the mystery of mixing and oceanic circulation, we will be able to simulate and predict the oceanic circulation and climate more accurately in the near future.

Water Types and Water Masses

WJ Emery, University of Colorado, Boulder, CO, USA

Synopsis

Historically, water masses were defined in terms of their temperature–salinity (TS), oxygen, and nutrient properties. The TS characteristic diagram became one of the primary methods of specifying water masses in terms of their TS extremes or singular TS values. Globally, TS curves are found to vary greatly closer to the surface. In the deep ocean, the global water mass distribution is related to the ‘global conveyor belt’ that circulates throughout the world ocean.

Introduction

Much of what is known today about the currents of the deep ocean has been inferred from studies of the water properties such as temperature, salinity, dissolved oxygen, and nutrients. These are quantities that can be observed with standard hydrographic measurement techniques that collect temperatures and samples of water with a number of sampling bottles strung along a wire to provide the depth resolution needed. Salinity or ‘salt content’ is then measured by an analysis of the water sample, which, when combined with the corresponding temperature value at that ‘bottle’ sample, yields temperature and salinity as functions of the depth of the sample. Modern observational methods have in part replaced this sample bottle method with electronic profiling systems, at least for temperature and salinity, but many of the important descriptive quantities such as oxygen and nutrients still require bottle samples accomplished today with a ‘rosette’ sampler integrated with the electronic profiling systems. These new electronic profiling systems have been in use for over 30 years, but still the majority of data useful for studying the properties of the deep and open ocean come from the time before the advent of modern electronic profiling systems. This knowledge is important in the interpretation of the data since the measurements from sampling bottles have very different error characteristics than those from modern electronic profiling systems.

This article reviews the mean properties of the open ocean, concentrating on the distributions of the major water masses and their relationships to the currents of the ocean. Most of this information is taken from published material, including the few papers that directly address water mass structure, along with the many atlases that seek to describe the distribution of water masses in the ocean. Coincident with the shift from bottle sampling to electronic profiling is the shift from publishing information about water masses and ocean currents in large atlases to the more routine research paper. In these papers, the water mass characteristics are generally only a small portion, requiring the interested descriptive oceanographer to go to considerable trouble to extract the information he or she may be interested in. While water mass distributions play a role in many of today’s oceanographic problems, there is very little research directed at improving our knowledge of water mass distributions and their changes over time.

What is a Water Mass?

The concept of a ‘water mass’ is borrowed from meteorology, which classifies different atmospheric characteristics as ‘air masses.’ In the early part of the twentieth century, physical oceanographers also sought to borrow another meteorological concept by separating the ocean waters into ‘warm’ and ‘cold’ water spheres. This designation has not survived in modern physical oceanography, but the more general concept of water masses persists. Some oceanographers regard these as real, objective physical entities, building blocks from which the oceanic stratification (vertical structure) is constructed. At the opposite extreme, other oceanographers consider water masses to be mainly descriptive words, summary shorthand for pointing to prominent features in property distributions.

The concept adopted for this discussion is squarely in the middle, identifying some ‘core’ water mass properties that are the building blocks. In most parts of the ocean, the stratification is defined by mixing both vertical and horizontal orientations of the various water masses that advect into the location. Thus, in the maps of the various water mass distributions, a ‘formation region’ is identified where it is believed that the core water mass has acquired its basic characteristics at the surface of the ocean. This introduces a fundamental concept first discussed by Iselin (1939), who suggested that the properties of the various subsurface water masses were originally formed at the surface in the source region of that particular water mass. Since temperature and salinity are considered to be ‘conservative properties’ (property is changed only at the sea surface), these characteristics would slowly erode as the water properties were advected at depth to various parts of the ocean.

Descriptive Tools: The Temperature–Salinity Curve

Before focusing on the global distribution of water masses, it is appropriate to introduce some of the basic tools used to describe these masses. One of the most basic tools is the use of property versus property plots to summarize an analysis by making extrema easy to locate. The most popular of these is the temperature–salinity (TS) diagram, which relates density to the observed values of temperature and salinity. Originally, the TS curve was constructed for a single hydrographic cast and thus related the TS values collected for a single bottle sample with the salinity computed from that sample. In this way, there was

a direct relationship between the TS pair and the depth of the sample. As the historical hydrographic record expanded, it became possible to compute TS curves from a combination of various TS profiles. This approach amounted to plotting the TS curve as a scatter diagram (Figure 1), where the salinity values were then averaged over a selected temperature interval to generate a discrete TS curve. The TS curve shown in Figure 1, which is an average of all of the data in a 10° square just northeast of Hawaii, shows features typical of those that can be found in all TS curves. As it turned out, the TS pair remained the same while the depth of this pair oscillated vertically by tens of meters, resulting in the absence of a precise relationship between TS pairs and depth. As sensed either by 'bottle casts' or by electronic profilers, these vertical variations express themselves as increased variability in the temperature or salinity profiles, while the TS curve continues to retain its shape, now

independent of depth. Hence, a composite TS curve computed from a number of closely spaced hydrographic stations no longer has a specific relationship between temperature, salinity, and depth.

As with the more traditional 'single-station' TS curve, these area average TS curves can be used to define and locate water masses. This is done by locating extrema in salinity associated with particular water masses. The salinity minimum in the TS curve of Figure 1 is at about 10°C , where there is a clear divergence of TS values as they move up the temperature scale from the coldest temperatures near the bottom of the diagram. There are two separate clusters of points at this salinity minimum temperature, with one terminating at about 13°C and the other transitioning to the warmest temperatures. It is this termination of points that results in a sharp turn in the mean TS curve and causes a very wide standard deviation. These

Figure 1 Example of TS 'scatterplot' for all data within a 10° square, with the mean TS curve (center line) and curves for one standard deviation in salinity on either side.

Figure 2 Simulated three-dimensional T–S–V (V – volume) diagram for the cold-water masses of the world ocean.

two clusters of points represent two different intermediate-level water masses. The relatively high salinity values that appear to terminate at 13 °C represent the Antarctic Intermediate Water (AAIW) formed near Antarctica, reaching its northern terminus after flowing up from the south. The coincident less salty points indicate the presence of North Pacific intermediate water moving south from its formation region in the northern Gulf of Alaska.

While there is no accepted practice in water mass terminology, it is generally accepted that a ‘water type’ refers to a single point on a characteristic diagram such as a TS curve. As introduced in this article, ‘water mass’ refers to some portion or segment of the characteristic curve, which describes the ‘core properties’ of that water mass. In the example given here, the salinity characteristics of the two intermediate waters were salinity minima, which were the overall characteristic of the two intermediate waters. We note that the extrema associated with a particular water mass may not remain at the same salinity value. Instead, as one moves away from the formation zone for the AAIW, which is at the oceanographic ‘polar front,’ the sharp minimum that marks the AAIW water that has sunk from the surface to about 1000 m in depth starts to erode, broadening the salinity minimum and slowly increasing its magnitude. By comparing conditions of the salinity extreme at a location with salinity characteristics typical of the formation region, one can estimate the amount of the source water mass that is still present at the distant location. Called the ‘core layer’ method, this procedure was a crucial development in the early study of the ocean water masses and long-term mean currents.

Many variants of the TS curve have been introduced over the years. One particularly instructive form is a ‘volumetric TS curve.’ Here, the oceanographer subjectively decides just how much volume is associated with a particular water mass. This becomes a three-dimensional relationship, which can then be plotted in a perspective format (Figure 2). In this plot, the two horizontal axes are the usual temperature and salinity, while the elevation represents the volumes with those particular TS characteristics. For this presentation, only the deeper water mass characteristics have been plotted, which can be seen by the restriction of the temperature scale from –1.0 to 4.0 °C. Arrows have been added to show just which parts of the ocean various features have come from. That the Atlantic is the saltiest of the oceans is very clear, with a branch to high salinity values at higher temperatures. The most voluminous water mass is the Pacific deep water, which fills most of the Pacific Ocean below the intermediate waters at about 1000 m.

Global Water Mass Distribution

Before turning to the TS curve description of the water masses, it is necessary to indicate the geographic distribution of the basic water masses. The reader is cautioned that this article treats only the major water masses, which most oceanographers accept and agree upon. If a particular region is of interest, close inspection will reveal a great variety of smaller water mass classifications; these can be almost infinite, as higher resolution is obtained in both horizontal and vertical coverages.

Table 1 presents the TS characteristics of the world's water masses. In the table are listed the area name, the corresponding acronym, and the appropriate temperature and salinity range. Recall that the property extreme erodes as it moves away from the source region, so it is necessary to define a range of properties. This is also consistent with the view that a water mass refers to a segment of the TS curve rather than a single point.

As is traditionally the case, the water masses have been divided into deep and abyssal waters, intermediate waters, and upper waters. While the upper waters have the largest property ranges, physically they occupy the least amount of ocean volume. The reverse is true of the deep and bottom waters, which have a fairly restricted range but occupy a substantial portion of the ocean. Since most ocean water mass properties are established at the ocean's surface, those water masses that spend most of their time isolated far from the surface will erode the least and have the longest lifetime. Surface waters, on the other hand, are strongly influenced by fluctuations at the ocean surface, which rapidly erode the water mass properties. In mean TS curves, as in [Figure 1](#), the spread of the standard deviation at the highest temperatures reflects this influence from the heat and freshwater flux exchange that occurs near and at the ocean's surface.

Accompanying the table are global maps of water masses at all three of these levels. The upper waters in [Figure 3](#) have

the most complex distribution, with significant meridional and zonal changes. A 'best guess' at the formation regions for the corresponding water mass is indicated by the hatched regions. For its relatively small size, the Indian Ocean has a very complex upper water mass structure. This is caused by some unique geographic conditions. First is the monsoon, which completely changes the wind patterns twice a year. This causes reversals in ocean currents, which also influence the water masses by altering the contributions of the very saline Arabian Gulf and the fresh Bay of Bengal to the main body of the Indian Ocean. All of the major rivers in India flow to the east and discharge into the Bay of Bengal, making it a very fresh body of ocean water. To the west of the Indian subcontinent is the Arabian Sea with its connection to the Persian Gulf and the Red Sea, both locations of extremely salty water, making the west side of India very salty and the east side very fresh. The other upper ocean water masses in the Indian Ocean are those associated with the Antarctic circumpolar current, which are found at all of the longitudes in the Southern Ocean.

As the largest ocean basin, the Pacific has the strongest east-west variations in upper water masses, with east and west central waters in both the North and South Hemispheres. Unique to the Pacific is the fairly wide band of the Pacific Equatorial Water, which is strongly linked to the equatorial

Table 1 Temperature–salinity (TS) characteristics of the world's water masses

Layer	Atlantic Ocean	Indian Ocean	Pacific Ocean
Upper waters (0–500 m)	Atlantic Subarctic Upper Water (ASUW) (0.0–4.0 °C, 34.0–35.0%) Western North Atlantic Central Water (WNACW) (7.0–20.0 °C, 35.0–36.7%) Eastern North Atlantic Central Water (ENACW) (8.0–18.0 °C, 35.2–36.7%) South Atlantic Central Water (SACW) (5.0–18.0 °C, 34.3–35.8%)	Bengal Bay Water (BBW) (25.0–29 °C, 28.0–35.0%) Arabian Sea Water (ASW) (24.0–30.0 °C, 35.5–36.8%) Indian Equatorial Water (IEW) (8.0–23.0 °C, 34.6–35.0%) Indonesian Upper Water (IUW) (8.0–23.0 °C, 34.4–35.0%) South Indian Central Water (SICW) (8.0–25.0 °C, 34.6–35.8%)	Pacific Subarctic Upper Water (PSUW) (3.0–15.0 °C, 32.6–33.6%) Western North Pacific Central Water (WNPWCW) (10.0–22.0 °C, 34.2–35.2%) Eastern North Pacific Central Water (ENPCW) (12.0–20.0 °C, 34.2–35.0%) Eastern North Pacific Transition Water (ENPTW) (11.0–20.0 °C, 33.8–34.3%) Pacific equatorial water (PEW) (7.0–23.0 °C, 34.5–36.0%) Western South Pacific Central Water (WSPCW) (6.0–22.0 °C, 34.5–35.8%) Eastern South Pacific Central Water (ESPCW) (8.0–24.0 °C, 34.4–36.4%) Eastern South Pacific Transition Water (ESPTW) (14.0–20.0 °C, 34.6–35.2%)
Intermediate waters (500–1500 m)	Western Atlantic Subarctic Intermediate Water (WASIW) (3.0–9.0 °C, 34.0–35.1%) Eastern Atlantic Subarctic Intermediate Water (EASIW) (3.0–9.0 °C, 34.4–35.3%) Antarctic Intermediate Water (AAIW) (2–6 °C, 33.8–34.8%) Mediterranean Water (MW) (2.6–11.0 °C, 35.0–36.2%) Arctic Intermediate Water (AIW) (–1.5 to 3.0 °C, 34.7–34.9%)	Antarctic Intermediate Water (AAIW) (2–10 °C, 33.8–34.8%) Indonesian Intermediate Water (IIW) (3.5–5.5 °C, 34.6–34.7%) Red Sea–Persian Gulf Intermediate Water (RSPGIW) (5–14 °C, 34.8–35.4%)	Pacific Subarctic Intermediate Water (PSIW) (5.0–12.0 °C, 33.8–34.3%) California Intermediate Water (CIW) (10.0–12.0 °C, 33.9–34.4%) Eastern South Pacific Intermediate Water (ESPIW) (10.0–12.0 °C, 34.0–34.4%) Antarctic Intermediate Water (AAIW) (2–10 °C, 33.8–34.5%)
Deep and abyssal waters(1500 m bottom)	North Atlantic Deep Water (NADW) (1.5–4.0 °C, 34.8–35.0%) Antarctic Bottom Water (AABW) (–0.9 to 1.7 °C, 34.64–34.72%) Arctic Bottom Water (ABW) (–1.8 to –10.5 °C, 34.88–34.94%)	Circumpolar Deep Water (CDW) (1.0–2.0 °C, 34.62–34.73%) Circumpolar surface waters	Circumpolar Deep Water (CDW) (0.1–2.0 °C, 34.62–34.73%) Subantarctic Surface Water (SASW) (3.2–15.0 °C, 34.0–35.5%) Antarctic Surface Water (AASW) (–1.0 to 1.0 °C, 34.0–34.6%)

Figure 3 Global distribution of upper waters (0–500 m). Water masses are in abbreviated form with their boundaries indicated by solid lines. Formation regions for these water masses are marked by cross-hatching and labeled with the corresponding acronym title.

upwelling, which may not exist in El Niño years. None of the other two ocean basins have this equatorial water mass in the upper ocean. The Atlantic Ocean has northern hemisphere upper water masses that can be separated east–west, while the South Atlantic upper water mass cannot be separated east–west into two parts. Note the interaction between the North Atlantic and the Arctic Ocean through the Norwegian Sea and Fram Strait. Also in these locations are found the source regions for a number of Atlantic water masses. Compared with the other two oceans, the Atlantic has the most water mass source regions, which produce a large part of the deep and bottom waters of the world ocean.

The chart of intermediate water masses in [Figure 4](#) is much simpler than that of the upper ocean water masses in [Figure 3](#). This reflects the fact that there are far fewer intermediate waters, and those that are present fill large volumes of the intermediate-depth ocean. The North Atlantic has the most complex horizontal structure of the three oceans. Here, intermediate waters form at the source regions in the northern North Atlantic. One exception is the Mediterranean Intermediate Water, which is a consequence of climatic conditions in the Mediterranean Sea. This salty water flows out through the Straits of Gibraltar at about 320 m depth, where it then descends to at least 1000 m, and maybe a bit more. It now sinks

Figure 4 Global distribution of intermediate water (550–1500 m). Lines, labels, and hatching follow the same format as described for [Figure 3](#).

below the vertical range of the less saline AAIW, instead joining with the higher salinity of the deeper North Atlantic Deep Water (NADW), which maintains the salinity maximum indicative of the NADW.

In the Southern Ocean, the formation region for the AAIW is marked as the location of the oceanic Polar Front, which is known to vary considerably in strength and location, moving the formation region north and south. That this AAIW fills a large part of the ocean can be clearly seen in all of the ocean basins. In the Pacific, the AAIW extends north to about 20° N, where it meets the North Pacific Intermediate Water (NPIW), as noted from Figure 1. The AAIW reaches about the same latitude in the North Atlantic, but it reaches only about 5° S in the Indian Ocean. In the Pacific, the northern intermediate waters are mostly from the North Pacific, where the NPIW is formed. There is, however, another intermediate water of smaller volume that is formed in the transition region west of California, mostly as a consequence of coastal upwelling. A similar intermediate water formation zone can be found in the South Pacific mainly off the coast of South America, which generates a minor intermediate water mass.

The deep and bottom waters mapped in Figure 5 are restricted in their movements to the deeper reaches of the ocean. For this reason, the 4000 m depth contour has been plotted in Figure 5, and a good correspondence can be seen between the distribution of bottom water and the deepest bottom topography. Some interesting aspects of this bottom water can be seen in the eastern South Atlantic. As the dense bottom water makes its way north from the Southern Ocean, in the east it runs into the Walvis Ridge, which blocks it from further northward extension. Instead, the bottom water flows north along the west of the mid-Atlantic ridge and, finding a deep passage in the Romanche Gap, flows eastward and then south to fill the basin north of the Walvis Ridge. A similar complex pattern of distribution can be seen in the Indian

Ocean, where the east and west portions of the basin fill from the south separately because of the central ridge in the bottom topography. In spite of the requisite depth of the North Pacific, the Antarctic Bottom Water (AABW) does not extend as far northward in the North Pacific. This means that some variant of the AABW, created by mixing with other deep and intermediate waters, occupies the most northern reaches of the deep North Pacific. Because the North Pacific is essentially 'cut off' from the Arctic, there is no formation region of deep and bottom water in the North Pacific.

The three-dimensional TS curve of Figure 2 indicated that the most abundant water, mass marked by the highest peak in this TS curve, corresponded to Pacific Deep Water. In Table 1, there is listed something called 'Circumpolar Deep Water' in the deeper reaches of both the Pacific and Indian Oceans. This water mass is not formed at the surface but is instead a mixture of NADW, AABW, and the two intermediate waters present in the Pacific. The AABW forms in the Weddell Sea as the product of very cold, dense freshwater flowing off the continental shelf. It then sinks and encounters the upwelling NADW, which adds a bit of salinity to the cold freshwater, making it even denser. This very dense product of Weddell Sea shelf water and NADW becomes the AABW, which then sinks to the very bottom and flows out of the Weddell Sea to fill most of the bottom layers of the world ocean. It is probable that a similar process works in the Ross Sea and some other areas of the continental shelf to form additional AABW, but the Weddell Sea is thought to be the primary formation region of AABW.

Summary TS Relationships

As pointed out in this article, one of the best ways to detect specific water masses is with the TS relationship, whether it is computed for single hydrographic casts or from a historical

Figure 5 Global distribution of deep and abyssal waters (1500 m–bottom). Contour lines describe the spreading of abyssal water (primarily AABW). The formation of NADW is indicated again by hatching, and its spreading terminus, near the Antarctic, by a dashed line, which also suggests the global communication of this deep water around the Antarctic.

accumulation of such hydro casts. Here, traditional practice is followed, and the summary TS curves are divided into the major ocean basins starting with the Atlantic (Figure 6). Once again, the higher salinities typical of the Atlantic can be clearly seen. The highest salinities are introduced by the Mediterranean outflow marked as MW in Figure 6. This joins with water from the North Atlantic to become part of the NADW, which is marked by a salinity maximum in these TS curves. The AAIW is indicated by the sharp salinity minimum at lower temperatures. The source water for the AAIW is marked by a dark square in the figure. The AABW is a single point, which now does not represent a 'water type' but, rather, a water mass. The difference is that this water mass has very constant TS properties that are represented by a single point in the TS curves. Note that this is the densest water on this TS diagram (the density lines are shown as the dashed curves in the TS diagram marked with the value of σ).

The rather long segments stretching to the upper temperature and salinity values represent the upper waters in the Atlantic. While this occupies a large portion of the TS space, it covers only a relatively small part of the upper ocean when compared to the large volumes occupied by the deep and bottom water masses. From this TS diagram, it can be seen that the upper waters are slightly different in the South Atlantic, the East North Atlantic, and the West North Atlantic. Of these differences, the South Atlantic differs more strongly from the other two than they do from each other.

By comparison with Figure 6, the Pacific TS curves (Figure 7) are very fresh, with all but the highest upper water mass having salinities below 35‰. The bottom property anchoring this curve is the circumpolar deep water (CDW), which is used to identify a wide range of TS properties that are known to be deep and bottom water but that have not been

identified in terms of a specific formation region and TS properties. As with the AABW, a single point at the bottom of the curves represents the CDW. The relationship between the AAIW and the PSIW can be clearly seen in this diagram. The AAIW is colder and saltier than is the PSIW, which is generally a bit higher in the water column, indicated by the lower density of this feature. There are no external sources of deep salinity like with the Mediterranean Water in the Atlantic. Instead, there is a confusing plethora of upper water masses that clearly separate the east–west and north–south portions of the basin. So, we have Eastern North Pacific Central Water (ENPCW) and Western North Pacific Central Water (WNPCW), as well as Eastern South Pacific Central Water (ESPCW) and Western South Pacific Central Water (WSPCW).

The 'central waters' all refer to open-ocean upper water masses. The more coastal water masses such as the Eastern North Pacific Transition Water (ENPTW) are typical of the change in upper water mass properties that occurs near the coastal regions. The same is also true of the South Pacific. In general, the fresher upper-layer water masses of the Pacific are located in the east, where river runoff introduces a lot of freshwater into the upper ocean. To the west, the upper water masses are saltier, as shown by the quasilinear portions of the TS curves corresponding to the western upper water masses. The Pacific Equatorial Water (PEW) is unique in the Pacific probably due to a well-developed equatorial circulation system. As seen in Figure 7, the PEW TS properties lie between those of the east and west central waters.

The Indian Ocean TS curves in Figure 8 are quite different from those of either the Atlantic or the Pacific. Overall, the Indian Ocean is quite a bit saltier than the Pacific but not quite as salty as the Atlantic. Also like the Atlantic, the Indian Ocean receives salinity input from a marginal sea as the Red Sea

Figure 6 Characteristic temperature–salinity (TS) curves for the main water masses of the Atlantic Ocean. Water masses are labeled by the appropriate acronym, and core water properties are indicated by a dark square with an arrow to suggest their spread. The cross-isopycnal nature of some of these arrows is not intended to suggest a mixing process but merely to connect source waters with their corresponding characteristic extrema.

Figure 7 Characteristic TS curves for the main water masses of the Pacific Ocean.

Figure 8 Characteristic TS curves for the main water masses of the Indian Ocean. All labels as in [Figure 6](#).

deposits its salt-laden water into the Arabian Sea. Its presence is noted in [Figure 8](#) as the black box marked RSPGIW (for Red Sea–Persian Gulf intermediate water). Added at the sill depth of the Red Sea, this intermediate water contributes to a salinity maximum that is seasonally dependent.

The bottom water is the same CDW that we saw in the Pacific. Unlike the Pacific, the Indian Ocean equatorial water masses are nearly isohaline above the point representing the CDW. In fact, the line that represents the Indian Equatorial Water (IEW) runs almost straight up from the CDW at about

0.0 °C to the maximum temperature at 20 °C. There is expression of the AAIW in the curve that corresponds to the South Indian Central Water (SICW). A competing Indonesian Intermediate Water (IIW) has higher temperature and higher salinity characteristics, which result in it having an only slightly lower density, creating the weak salinity minimum in the curve transitioning to the Indian Upper Water (IUW). The warmest and saltiest part of these TS curves represents the Arabian Sea Water (ASW) on the western side of the Indian subcontinent.

Discussion and Conclusion

The descriptions provided in this article cover only the most general of water masses, their core properties, and their geographic distribution. In most regions of the ocean, it is possible to resolve the water mass structure into even finer elements describing more precisely the differences in temperature and salinity. In addition, other important properties can be used to specify water masses not obvious in TS space. While dissolved oxygen is often used to define water mass boundaries, care must be taken as this nonconservative property is influenced by biological activity and the chemical dissolution of dead organic material falling through the water column. Nutrients also suffer from modification within the water column, making their interpretation as water mass boundaries more difficult. Characteristic diagrams that plot oxygen against salinity or nutrients can be used to seek extrema that mark the boundaries of various water masses.

The higher vertical resolution property profiles possible with electronic profiling instruments also make it possible to resolve water mass structure that was not even visible with the lower vertical resolution of earlier bottle sampling. Again, this complexity is merited only in local water mass descriptions and cannot be used for global-scale descriptions. At this global scale, the descriptive data available from the accumulation of historical hydrographic data are adequate to map the large-scale water mass distribution, as has been done in this article.

Synopsis

The optical spectroscopic instruments employed in remote sensing of the atmosphere were invented more than 100 years ago, and it is remarkable how little the fundamental concepts embodying these instruments have changed. However, the technologies involved in using these concepts are totally different. About 50 years ago, photoelectric detection of photons became possible and with this an understanding of what the responsivity of an optical system really means. This caused a revolution in the field that can be called interferometric spectroscopy, at just about the same time as the space age began. About 25 years ago, array detectors, particularly CCDs, began to be used in space instruments. The application of existing instruments as spectral imagers changed the technology again. In this article, the fundamental concepts are reviewed, their characteristics and then their application, including imagers for remote sensing, are described.

Introduction

The sun that sustains the environment also makes it possible to study and monitor the atmosphere through optical remote sensing, by taking advantage of its incredibly broad electromagnetic spectrum. The shorter wavelengths, in the far and extreme ultraviolet, are absorbed in the high atmosphere, driving its photochemistry, which in turn produces its own spectrum of emitted radiation, called airglow. Light in the visible region reaches the Earth's surface because the primary atmospheric constituents of molecular oxygen and nitrogen are transparent to solar radiation but the minor constituents such as carbon dioxide, ozone, and water vapor do absorb at specific wavelengths, providing a means of detecting them from the light absorbed or reflected back into the space. Superimposed on this is molecular and particulate scattering from the atmosphere. The sun provides an indirect but equally important method of optical remote sensing from the atmosphere's thermal infrared radiation, from those minor constituents, or from the Earth's surface itself. As a result, instruments covering a wide range of wavelengths can be used to determine species concentrations in the upper atmosphere, from the troposphere through the stratosphere and mesosphere, up into the uppermost region, the thermosphere.

What the researcher needs to know in order to deduce these concentrations is the number of photons emitted (the volume emission rate), or absorbed, per unit volume of the

atmosphere. What is observed is the line integral (the integrated emission rate) of these quantities along the line of sight, but from a set of line integrals, the true height profiles can be retrieved through numerical inversion.

In addition to retrieving constituent concentrations, derived quantities can be determined as well. Thermal emission from the atmosphere is a function of its temperature and the species' concentrations, following the physics of blackbody radiation. If the species has a known mixing ratio (fractional concentration in the atmosphere) as is the case for CO₂, the temperature may be determined. Once this is known, the concentrations of unknown minor constituents may be obtained from their thermal emission. Temperature profiles may also be determined from the molecular scattering of the atmosphere, called Rayleigh scattering, as the observed scale height is a function of the temperature. In the upper atmosphere, rotational temperatures, which accurately represent kinetic temperatures, can be obtained from the relative strengths of rotational lines for molecular emission and from atoms from their line widths, where those are dominated by the Doppler shifts of their thermal motion. In a similar manner, winds may be obtained from the Doppler shifts corresponding to the bulk motion of the observed atmosphere, superimposed on their random motions.

All of this capability depends on the ability of optical remote sensing instruments to observe the atmospheric spectra with the required responsivity and spectral resolution. Going

back over 100 years, the diffraction grating spectrometer along with the Fabry–Perot and Michelson interferometers were well-known instruments. With the advent of photoelectric detection, a large number of alternative approaches were explored, but the recent needs in remote sensing have brought these three back to the fore again, including an interesting hybrid, in part because of the current emphasis on imaging. In this article, the conceptual bases of the different instruments are described and the factors involved in choosing the best instrument for a particular application are discussed.

Responsivity and Superiority of Optical Spectroscopic Systems

The responsivity R of an optical system is the ratio of its output signal, say the number of electrons collected during the observation, to the input radiance. It is given by $R = A \Omega \tau q T$, where A is the area of the instrument opening aperture, Ω is the solid angle of observation, τ is the instrument transmittance, q is the detector quantum efficiency, and T is the time duration of the observation. Since the radiance is what is presented by the atmosphere, the researcher has control only over the responsivity, which determines the error of the observation. The $A\Omega$ was called the *étendue* by Pierre Jacquinot, a pioneer in understanding the determining factors in responsivity, and it is absolutely fundamental as τ and q are determined purely by technical considerations. Ω is the spatial resolution element required for the measurement and A is as large as necessary, compatible with the available budget but also with the allowed instrument volume and mass. But Ω cannot be chosen at will; it is restricted by the dispersive element within the basic spectroscopic system. Normally one or more telescopes transform the solid angle of the field of view on the atmosphere to its value within the dispersing element. But the *étendue* here is the same as in the field of view; *étendue* is conserved throughout an optical system. The reason for the linkage between solid angle and spectral resolution is that for any dispersing element the transmitted wavelength, λ , changes with off-axis angle; the spectral resolution $d\lambda$ is often described in terms of the ‘resolving power,’ simply $\mathcal{R} = \lambda/d\lambda$. Jacquinot showed that for each spectroscopic instrument, the value of $\Omega \mathcal{R}$ has a fixed value; for the interferometers he considered, both Fabry–Perot and Michelson, the value is 2π . Jacquinot described this restriction in terms of what he called the ‘luminosity resolving power product,’ luminosity being $A\Omega$. In ‘Spectral Imaging of the Atmosphere,’ the author proposed that $\Omega \mathcal{R}$ be called the ‘superiority’ (S) of the instrument, because it does not include the arbitrary factor A .

Jacquinot’s statement that the superiority of each type of optical instrument is fixed was formulated when spectroscopic instruments had a single field of view, and all of the corresponding output photons were collected by a single detector; for those circumstances, the statement is absolute. However, in subsequent developments, additional factors were recognized. The first of these is ‘multiplexing’ and the second is ‘field widening.’ As well, the considerations change for imaging instruments, which are now very much at the forefront of optical remote sensing. All of these factors are described in what follows for specific instruments. These are the (1)

diffraction grating spectrograph (DGS), (2) Fabry–Perot spectrometer (FPS), (3) scanning Michelson interferometer generally known as the Fourier transform spectrometer (FTS), (4) Doppler Michelson interferometer (DMI), and (5) spatial heterodyne interferometer (SHI). It is difficult to be consistent with the nomenclature. The author prefers to call an instrument a spectrometer if its immediate output is a spectrum and a spectrograph where the entire spectrum is recorded at once, originally on film, now on array detectors. A device which produces an interferogram, which requires a Fourier transformation to obtain a spectrum, is herein called an interferometer. However, in the above list, historical precedent is recognized.

The Diffraction Grating Spectrograph

The diffraction grating spectrometer, as described by Jacquinot, has a superiority $S = \beta \tan i$, where β is the angular length of the slit and i is the angle of incidence onto the grating (for simplicity a Littrow arrangement is used where the angles of incidence and diffraction are equal). From basic considerations S must be around 0.1, which is much less than the 2π for the FPS and the FTS. This profound result is what propelled interferometric spectroscopy into prominence in the 1960s, the effects of which are still being incorporated into flight experiments.

However, in remote sensing instruments, the DGS, in which the exit slit is replaced by an array detector, has produced some impressive results. One example is the OSIRIS instrument on the Odin satellite, another is the SCIAMACHY instrument on the ENVISAT satellite, another is the MAESTRO instrument on Canada’s SCISAT satellite, and for the future the OMPS (Ozone Mapping and Profiler Suite) instrument is now in flight on the NASA NPP (National Polar-orbiting Partnership satellite) launched in 2011.

Suppose a CCD detector is employed, with 256×256 pixels. Also suppose that the slit width corresponds to the size of 1 pixel so that the slit corresponds to one column of pixels. Each of these 256 columns can simultaneously measure 256 wavelengths, which increases the responsivity by a factor of 256, this enhancement is called multiplexing. But as an imager, the spatial resolution element can now be just 1 pixel, reducing the signal by $1/256$, compensating exactly for the multiplex increase. Thus, a one-dimensional image is obtained with the same responsivity as for the single-field whole-slit measurement. Multiplexing is therefore an important factor to consider.

Fabry–Perot Spectrometer

The FPS comprises a cavity, called an etalon, formed by two parallel surfaces with coatings of reflectivity slightly less than unity, within which multiple reflections take place. At angles and wavelengths where the multiply-reflected waves are in phase the transmitted signal is strong, and where they are out of phase the light is reflected back to the source. Thus, the etalon acts as a filter, transmitting wavelength λ , as given by eqn [1], where m is the order of interference, n is the refractive index of the cavity medium, normally air, t is

the thickness of the cavity, and θ is the angle of the ray with the etalon normal, measured inside the cavity.

$$m\lambda = 2nt \cos \theta \quad (1)$$

The quantity $2nt$ is called the optical path difference (OPD); it is a measure of the delay time between reflected rays expressed as the distance in vacuum the light would travel in the same time. The quantity m is the number of wavelengths that fit within the cavity. For most applications, the order of interference varies from about 1000 (low resolution) to 100 000 (high resolution). The interference filter is a particular type of low-resolution etalon, so the Fabry–Perot etalon has a wide range of applications. For each value of m , λ is different; thus, the etalon has a spectral transmittance resembling a Dirac comb, with passbands equally separated in the spectrum by an amount known as the free spectral range, $\Delta\lambda$. These multiple passbands must be dealt with in some way if the spectrum is to be measured unambiguously. Since λ is a constant for a constant θ , the transmitted radiation for a given wavelength/order forms a ring of constant θ about the etalon normal in the focal plane. Each order produces a ring of a different radius, forming the familiar Fabry–Perot ring pattern.

The shape of the spectral passband function (its overall transmittance F) is best expressed in terms of wave number, $\sigma = \lambda^{-1}$, where r is the individual surface reflectance, τ the transmittance, and Δ is the OPD of the etalon; $F(\sigma)$ is given by

$$F(\sigma) = \frac{[\tau/(1-r)]^2}{1 + [4r/(1-r)^2]/\sin^2 \pi\sigma\Delta} \quad (2)$$

The transmittance peaks where $\sin^2 \pi\sigma\Delta = 1$, which occurs whenever σ increases by $(1/\Delta)$. The transmittance function is shown in **Figure 1**, for an air-spaced etalon of 2.5 cm spacing having $r = 0.9$; the free spectral range is $1/(2 \times 2.5) = 0.2 \text{ cm}^{-1}$. The full width at half maximum (FWHM) is equal to the free spectral range divided by the finesse f , given by **eqn [3]**,

$$f = \frac{\Delta\sigma}{\text{FWHM}} = \frac{\pi\sqrt{r}}{1-r} \quad (3)$$

which for the reflectance of 0.9 used in **Figure 1** is equal to 29.8.

Figure 1 FPS passband response function for an etalon with reflectance of 0.9, corresponding to a finesse of 29.8.

Although the finesse is a constant for a given etalon, the spectral passband width may be chosen by adjusting the etalon separation. This flexibility is one of the advantages of the FPS, which in its simplest form is just an etalon followed by a lens, with a circular aperture at its focal point and a detector behind it. The sharpness of the passband peaks allows the FPS to be used as a spectrometer, but to produce a spectrum the etalon must be scanned. According to **eqn [1]**, to change λ one must change n or t or θ . The refractive index n can be changed by changing the gas pressure in an air-spaced etalon. For a high-resolution etalon, about 1 atmosphere of pressure ($\sim 100 \text{ kPa}$) change is required to scan the spectrum by one order; this was a common technique for ground-based instruments. Varying t involves the mechanical movement of one of the etalon plates; in current instruments, this is done with piezoelectric positioners cemented between the plates. For high accuracy, capacitors are used to sense the spacing and control the piezoelectric voltage in a feedback system. This approach works well at high or low resolution, since a movement of $\lambda/2$ causes a scan through one free spectral range.

To create a single passband with an FPS, multiple etalons can be used. A triple etalon system was used for the High-Resolution Doppler Imager (HRDI) on the Upper Atmosphere Research Satellite (UARS), for middle atmosphere wind measurement.

Finally, λ can be changed by changing θ , and this is readily achieved through the use of an array detector, in which radial distance is equivalent to wavelength, though with a quadratic scale. However, this has the very nice consequence that equal spectral widths correspond to equal areas on the detector array. The disadvantage of this approach is that the rings become very narrow at the edges of the array, requiring small pixels, and in the readout, the readout noise is accumulated for each pixel. This limitation has been relaxed through the use of the CLIO (circle to line imaging optical system), in which a hollow cone is used to image the circular fringes into straight lines that correspond to the pixel layout on the CCD. Because the CCD charges can be binned, that is, added together in a noise-free way on the chip before reaching the output register, this reduces the noise significantly in the final spectrum.

The superiority $S = 2\pi$ for an air-spaced etalon is increased to $S = 2\pi n^2$ where solid etalons are employed, such as with interference filters.

Scanning Michelson Interferometer (Fourier Transform Spectrometer)

The Michelson interferometer shown in **Figure 2** also forms a cavity of thickness t , but this is done in a different way from the FPS. The incoming light is split into two beams created in a beamsplitter as shown in **Figure 2**, each of which suffers a transmission and reflection through the beamsplitter before recombination and registration at the detector. The OPD is the same as given in **eqn [1]** for the FPS but in operation the mirror M_1 is moved over relatively large distances and the output signal as a function of Δ is measured from 0 to some maximum value. The output record, with the constant term removed, is called an interferogram. For a monochromatic signal of infinitesimal line width, the output is simply a sinusoid of constant amplitude,

Figure 2 An ordinary Michelson interferometer with a beamsplitter, a fixed mirror M_2 , and a movable mirror M_1 , which is shown in two positions, indicated by M_1 and M_1' . For position M_1 , the combined rays are collinear, corresponding to 0 OPD, while for position M_1' , the rays are displaced, producing an OPD of $2nt \cos \theta$, where θ is the off-axis angle of the rays.

one cycle for every $\lambda/2$ of mirror motion. If the spectral line has a finite width, then the amplitude of the cosinusoid decays with increasing OPD because the different components of the line progressively get out of phase. If the spectrum contains two different wavelengths, there will be two superposed cosinusoids of different periods; for a complex spectrum, many cosinusoids will be superimposed. The spectrum therefore may be retrieved by a Fourier transform as in eqn [4].

$$F(\sigma) = \int_{-\infty}^{\infty} I(\Delta) \cos(2\pi\sigma \Delta) d\Delta \quad (4)$$

In actual practice, it is more complicated than this. The interferogram cannot be measured to infinity but only to some $\Delta_{\max}$. A real instrument has dispersion in its optical elements so that the cosinusoids are phase shifted by amounts that are dependent on wavelength, and the phase must be retrieved. This can be done by measuring from $-\Delta_{\max}$ to $+\Delta_{\max}$ and doing both sine and cosine transforms, but this is an inefficient process. It is preferable and feasible to use a small part of the interferogram about 0 OPD to determine the phase shifts, and to use this to create a corrected interferogram that is symmetric about 0, and for which a cosine transform may be used.

This instrument, which was used by Michelson to measure the separation of very closely spaced lines and the widths of spectral lines, has enjoyed a spectacular increase in attention and use, beginning in the 1960s. As noted, its $S = 2\pi$ gave it a substantial responsivity but it also has a multiplex advantage as every spectral element is simultaneously observed for the full duration of the observation. Examples of highly successful observations are from the ATMOS instrument, flown on the space shuttle, and the ACE-FTS, flown on Canada's SCISAT spacecraft. The challenge in any such instrument is the precision movement of the mirror. For ACE-FTS, this was done using a dual pendulum approach; although not shown in the figure,

the two prisms were mounted on two arms of a pendulum, rotating about a fixed pivot as is shown in the instrument configuration of Figure 3. The method of observation of the absorption spectrum of the atmosphere was solar occultation, in which the sun is observed as it sets or rises at the Earth's limb. With this large radiance, high resolution and ample responsivity were accomplished with a very small instrument (35 kg). Other impressive examples are the MIPAS instrument on ENVISAT, which observed thermal emission from the atmosphere with a resolution of 0.035 cm^{-1} , requiring a large instrument (170 kg), and the Japanese FTS on the GOSAT spacecraft.

Doppler Michelson Interferometer

The Michelson interferometer has the remarkable property that it can be field widened. Figure 2 shows an ordinary Michelson interferometer set to 0 OPD for mirror M_1 ; the rays emerge collinearly, making the OPD independent of angle. When the mirror is moved to M_1' , the emerging rays are no longer collinear and the OPD becomes a strong function of off-axis angle. In Figure 4, an OPD is introduced through the use of a refractive plate in one arm, but the rays still emerge collinearly and the OPD is nearly independent of angle; 'nearly' because the position of the virtual mirror does depend weakly on angle. Analytically the field widening is expressed in eqn [5] for the more general case of refractive materials of thickness t_1 and t_2 in the two arms, having refractive indices of n_1 and n_2 , respectively.

$$\frac{\Delta}{2} = n_1 t_1 - n_2 t_2 - \frac{\sin^2 i}{2} \left(\frac{t_1}{n_1} - \frac{t_2}{n_2} \right) - \frac{\sin^4 i}{8} \left(\frac{t_1}{n_1^3} - \frac{t_2}{n_2^3} \right) + \dots \quad (5)$$

If $t_1 n_2 = t_2 n_1$, the instrument is said to be field widened as the term in $\sin^2 i$ vanishes and the path difference is then independent of angle to fourth order as shown in the equation.

The superiority of the field-widened Michelson interferometer is given by $S = 4\pi n^2 \sqrt{\mathfrak{R}}$. This over rules the Jacquinot statement as the superiority is not constant; it increases with increasing resolving power, which makes it ideal for high-resolution measurements, such as Doppler measurements of line width (temperature) and shift (winds). The off-axis angle inside the instrument can be as much as 6° or even larger.

This approach was used in the WIND Imaging Interferometer (WINDII) flown on NASA's UARS mission from 1991 to 2003 for the measurement of winds in the upper atmosphere, using airglow as a Doppler target. By choosing appropriate pairs of glasses for the two arms, the interferometer was made achromatic and thermally stabilized. It was fabricated as a 'solid' interferometer, which is all glass components cemented together except for an air space in front of the phase stepping mirror. This mirror was stepped in OPD phase increments of 90° to allow the measurement of spectral line phase and thus the wind, from the cosinusoids of single airglow lines.

Spatial Heterodyne Spectroscopy

This approach has become recognized within the last decade as able to fill significant niches in the capability of atmospheric remote sensing. Remarkably it comprises elements from almost

Figure 3 The ACE-FTS instrument flown on the Canadian SCISAT mission. The cube corner prisms were mounted on the two arms of a dual pendulum so that as one prism approached the beamsplitter the other receded. This doubled the OPD for a given reflector motion. The double-pass layout gave a further doubling. With permission from Spectral Imaging of the Atmosphere, Elsevier. Courtesy of ABB Bomem.

Figure 4 A field-widened Michelson interferometer. The ray paths are similar to those in Figure 2(a) except the mirror M_2 has been replaced by a glass plate, with the apparent reflection taking place from the virtual mirror within it. The rays emerge colinearly so the OPD is nearly independent of incident angle, even though there is a finite path difference.

every instrument discussed up to this point. It dates back to an instrument called SISAM (Spectromètre Interférentiel à Sélection par l'Amplitude de Modulation) by its inventor, Pierre Connes, of Jacquinot's laboratory. Connes recognized that by replacing the mirrors of an ordinary Michelson interferometer with diffraction gratings, the Littrow wavelength would be unmodulated, while other wavelengths would, say by oscillating a retardation plate inside the instrument. Then by rotating the gratings in synchronism, one could bring different wavelengths sequentially into zero modulation and so have a spectrometer – with no need for Fourier transforms. Unfortunately, rotating the gratings in synchronism proved to be impractical. The motivation at that time was to avoid the use of the large computers that were then required for the FTS instruments. Some 40 years later, Fred Roesler and John Harlander implemented a practical version in which the output was imaged onto a two-dimensional array. It can be shown, as in Figure 5, that the wave fronts coming from the two gratings cross at an angle, creating an OPD along the wave fronts. For the Littrow wavelength, this angle is 0, yielding a flat field across the detector (no modulation). For a wavelength different by $\delta\sigma$, the output beams from the two gratings create a co-sinusoidal pattern of one spatial wavelength across the detector. Increasing the wavelength difference to $2\delta\sigma$ increases the angle between the wave fronts and creates two spatial waves across the detector. Thus, a spatial interferogram is recorded, which can be Fourier transformed to yield a spectrum with a number of spectral elements corresponding to one-half the number of pixels across the detector (by Shannon's theorem). The SHS device is an FTS with no moving parts. A true interferogram is obtained, the only difference being that zero

Figure 5 Explanation of the SHS approach after Harlander et al. (1992).

frequency is now the heterodyne frequency. The spectral range is limited, but this is offset by the fact that the desired wavelength range can be selected at will because of the heterodyne capability. In remote sensing terms, a separate instrument is needed for every species to be observed, but this is acceptable given the very high responsivity as this device can also be field widened.

The first flight SHS instruments were fabricated using the same 'solid' instrument approach pioneered by WINDII, where all the optical elements are cemented together, possible because there are no moving parts. These instruments are more formally said to be 'monolithic.' Englert and colleagues at the US Naval Research Laboratory have demonstrated that the SHS configuration may be operated at a near fixed but large OPD by inserting a plate of glass into one arm, as was done with WINDII, allowing the measurement of winds. In this case, a region of the interferometer is recorded, from which a true spectrum cannot be obtained, as 0 OPD is not included. However, the winds can be obtained from the phase shifts, as for WINDII. The advance over WINDII is, however, that the phase shifts can be obtained simultaneously for more than one line. This approach is currently being investigated by the author and colleagues as the optimum way to measure winds in the stratosphere,

using ozone as a Doppler target. For ozone, even with a narrow filter, it is difficult to isolate a single spectral line. But also, for wind measurements, the atmospheric lines and the phase calibration spectral lamp line can be recorded in the same interferogram, reducing the susceptibility to thermal phase drift.

Imaging from Space

As implied earlier, almost all remote sensing optical instruments now incorporate imaging, whether it be conventional nadir viewing imaging (mapping) or imaging vertical altitude profiles at the Earth's limb, both from a low-Earth orbit. A more challenging example is whole-Earth imaging from geostationary orbit (GEO) as has been done with GOES-X and will be done with GOES-R. An even more challenging approach is imaging the polar cap from highly elliptical orbits (HEO) of which the Molniya orbit is the best known. In imaging it is necessary to think of responsivity per pixel.

For a simple camera imager, it can be shown that the responsivity per pixel depends only on the f/number of the

camera lens and the area of the pixel. However, in order to achieve this, the solid angle defined by the camera must be accepted by the dispersing element; if this is not possible then an alternative approach must be sought. Some of these are indicated below, where the five types of instruments discussed in the previous sections are evaluated for their imaging capabilities.

Diffraction Grating Spectrograph

The DGS has a low superiority as discussed earlier, but its geometry has some unique advantages that can be applied to imaging. As shown in Figure 6(a), the optical input is a slit that is imaged on the target. Because the 'diffraction' effect sends different wavelengths off the grating at different angles, the output is a rectangle that can be imaged onto an array detector, also as shown in Figure 6(a). One dimension of the detector is wavelength, the other space – the output is a one-dimensional image in which for each spatial resolution element (pixel) the entire spectrum covered is available. To create a two-dimensional image in nadir viewing the slit can be moved along the spacecraft track perpendicular to its long axis simply by the motion of the spacecraft, called push broom scanning. For

GEO or HEO orbits, a scanning mirror can be used to scan the slit across the target. If the étendue is insufficient to cover the entire image then a cross-scanning mirror can be added to achieve multiple strip scans. For GEO, for example, the Earth is scanned in strips with two mirror motions, one horizontal and one vertical, each strip having a length determined by the angular dimensions of the slit. This is feasible because long scan times are permissible, e.g., 15 min. To cover the spectrum, a typical scenario is to use multiple spectrographs, each defining one spectral region, with the specific spectral bands determined by the placement of the array detectors at the exits of each spectrograph.

Fabry–Perot Spectrometer

As already discussed, the FPS category includes interference filters and the off-axis wavelength change with angle follows the same basic eqn [1]. If the FPS is placed in front of the camera lens then each pixel will have its own passband function which must be taken account in the image analysis. Another approach is to use telecentric optics; image-space telecentric lenses have an exit pupil infinitely far in front of the lens, the result of which is that all of the chief rays (the rays passing through the center of the aperture stop) have a 0 angle of incidence. This minimizes the off-axis angle effect through the FPS and makes the passband the same for all pixels. This is a simple and feasible method for low resolution as shown in Figure 6(b).

One can alternatively utilize the off-axis effect for wavelength scanning. HRDI used the radial dimension for Doppler shifts (and winds) while using a gimbaled telescope for scanning. Working at significant off-axis angles with an FPS means covering multiple orders; this is limited by the fact that the outermost rings in the FPS ring pattern become very narrow, making demands on the detector pixel size. The CLIO configuration as discussed earlier offers a solution to this problem; as employed in NASA's TIMED mission in the TIDI (Timed Doppler Interferometer) which utilized different orders for the four different telescope directions. For two-dimensional imaging, a raster-type scan is required, as indicated in Figure 6(c).

Fourier Transform Spectrometer

The scanning Michelson interferometer, or FTS, covers a wide spectral range at high resolution and enjoys the multiplex advantage as well as a superiority of 2π , but the imaging capability is limited by how far one can go off-axis and still obtain a valid interferogram, as illustrated in Figure 6(c). Subimages could be created by acquiring suites of interferograms near the optical axis and then be used to create a full two-dimensional image by a raster scan using two mirrors as shown in the figure.

Doppler Michelson Interferometer

Because of its field widening, the DMI is a true imager in that it can tolerate sufficiently large off-axis angles to meet the solid angle requirements of the camera for most applications. The spectral information, which for WINDII was the interferogram

Figure 6 Depiction of ways in which the five different spectroscopic devices discussed in this manuscript may be implemented as spectral imagers. (a) The diffraction grating spectrograph, (b) the low-resolution FPS, (c) the high-resolution FPS, (d) the DMI, and (e) the SHS.

phase, was obtained by acquiring four images with different OPD values using a stepping mirror. This has the disadvantage that the images are taken sequentially, rather than simultaneously, but has the advantage that the derived quantity, the wind, was obtained independently from each pixel, yielding a two-dimensional image of wind as is shown in [Figure 6\(d\)](#). In practice, because of the low available data rate and the desire to measure winds at low emission rates, the WINDII horizontal information was collapsed onto a single profile.

Spatial Heterodyne Spectroscopy

The SHS instrument is a powerful version of the FTS, operating over limited specific wavelength bands and as such, the motivation to employ it for imaging, as for the FTS, is very strong. It is similar to the DGS in that with a two-dimensional array detector one acquires a complete interferogram (and thus spectrum) for each row of pixels. This works well for limb viewing where a single vertical profile is all that is required although there is a potential problem in that the light contributing to the interferogram comes from a spatial region spread out horizontally across the limb. While the atmosphere is approximately horizontally homogeneous it is not entirely so. The solution to this problem is to use an anamorphic imaging system in which one of the two imaging directions is compressed with respect to the other as shown in [Figure 6\(e\)](#) so that a smaller region of atmosphere is used to generate each interferogram. If this is done then the compressed direction is analogous to the DGS slit and the scanning methods described for it above may be used.

Summary

Over the 50 years or so of the space age, a wide variety of optical devices has been used for the remote sensing of the atmosphere. However, over time there has been a trend toward a small number of basic instruments each configured for a specific type of measurement. Those discussed here are (1) the diffraction grating spectrometer, (2) the FPS, (3) the scanning Michelson interferometer/Fourier transform spectrometer, (4) the DMI, and (5) the spatial heterodyne interferometer. A comparison of the inherent responsivities of these instruments has been presented, based on the Jacquinot principle of superiority. When applied to imaging instruments, the

considerations are somewhat different as the imposition of the required solid angle of observation by the imager itself dominates. Nevertheless the dispersing device must be capable of meeting the same solid angle requirement. This can always be achieved if the instrument is sufficiently large or if appropriate mirror scanning methods are used. It is expected that the approaches to optical remote sensing will stabilize in the coming decade.

Introduction

The airglow and, in polar regions, the aurora are faint and generally diffuse optical glows originating from photochemical reactions occurring in the Earth's upper atmosphere at altitudes above ~ 70 km. During daytime and twilight there is an additional source of airglow due to resonant scattering of sunlight. The airglow provides a means of remote sensing the conditions within its atmospheric source region. Optical instruments are used to measure properties of the emitted radiation, from which properties of the atmosphere may be inferred.

All optical instruments measure light intensity and, by repeated measurement, can also measure the time variation of intensity. Further, most instruments are designed to resolve the intensity distribution of the incident radiation with respect to one or more other parameters such as viewing direction, wavelength, or polarization state.

Airglow processes emit light over a wavelength range from ultraviolet through infrared. The propagation and detection requirements for light vary greatly over this range. Also, the dispersing components that are required differ, depending upon the spectral character of the incident radiation and upon how it is to be resolved. Together, these considerations have resulted in an enormous variety of optical instrumentation for studying the airglow. Some of the major instrument types will be described here, and a brief discussion of some important design considerations will be presented.

Common Instruments

Photometers

Photometers, which measure optical brightness within a single field of view, are the simplest optical instruments for measuring the airglow. Most photometer applications include a narrow-band filter, to isolate a single spectral emission feature. Ideally, a narrow-band photometer would also sample some wavelength adjacent to the emission line of interest, to estimate the brightness of background light that arises for example from the Moon, streetlights, twilight, etc. Many remote sensing techniques use ratios of brightness of two or more emission lines. The required measurements can be made either by swapping several filters in a single photometer or by operating several complete photometers in parallel.

Although applications exist for wide-field photometers, fields of view subtending at most a few degrees are more common. Such narrow-field photometers may be placed on steerable mounts, or be set to view in some fixed direction (typically in either the geographic or the geomagnetic zenith.) One very common configuration is to arrange for one or more narrow-field, narrow-band photometers to view the sky via a spinning mirror that sweeps their field(s) of view along a north–south meridian. This yields a sequence of latitudinal

'cuts' through the two-dimensional airglow or auroral luminosity pattern, as depicted in [Figure 1](#).

2-D Imagers

Airglow and auroral imagers are similar to photometers, except that they use a two-dimensional imaging detector to resolve the airglow brightness with respect to two angular directions in the sky. Any field of view is possible, up to a 180° all-sky view. Once again, an airglow imager operating at visible wavelengths would normally use a narrow-band filter to select a particular emission line. In the near infrared it is possible to use a broader bandpass filter to select groups of lines from OH rotational bands.

Spectrometers

Simple spectrometers measure the spectral distribution of incident radiation from a single field of view. Various optical components can be used to disperse the light according to wavelength, including prisms, gratings, Fabry–Perot etalons, or Michelson interferometers. Two levels of resolution are useful for airglow and auroral applications. For applications that merely require line intensities, spectral resolutions of 0.1 to several nanometers are adequate. Much higher resolutions (3 pm or less) are required to determine the Doppler shifts and Doppler widths of spectral lines. These results can then be used to estimate upper-atmospheric winds and temperatures respectively.

The world's most sensitive optical spectrometers are those attached to large astronomical telescopes. During observations, celestial targets are usually positioned upon the spectrometer slit so that a portion of the adjacent 'dark sky' is also included; this is used for background subtraction from the celestial spectrum. As the telescope must look through the upper atmosphere, the background measurement also yields an airglow spectrum with unparalleled sensitivity (it is not uncommon for a large telescope to integrate a single spectrum for several hours). This technique has allowed emission lines whose very existence was once a mere theoretical prediction to be observed for the first time in airglow spectra.

Hyperspectral Imagers

Hyperspectral imagers combine the spectral resolution of spectrometers with the angular resolution of conventional imagers. That is, one- or two-dimensional images are recorded, with the spectral distribution of the source radiation independently resolved at each image pixel. Subsequently, the spectrum recorded in each pixel is analyzed to derive an estimate of some geophysical parameter (such as atmospheric wind or temperature). These parameter estimates can then be projected back onto the longitude and latitude locations of the original image pixels. The result is a geographic map of

Figure 1 Data recorded by a four-channel meridian-scanning photometer. The four upper panels show, for four different optical wavelengths, the brightness of airglow and auroral emissions as functions of viewing angle along the local geomagnetic meridian. A viewing angle of 0° corresponds to the geomagnetic north horizon, whereas 180° corresponds to the south horizon. Brightness data from 100 successive mirror scans are shown in a 'stacked' format, with corresponding sample times indicated along the left-side axis. The lower panel shows a longer time-history for three of the four channels. The horizontal axis in this presentation represents time, whereas the vertical axis represents viewing angle along the meridian. Each pixel in this image is brightness-modulated in three colors. The red brightness is proportional to the measured sky brightness at $\lambda = 630.0$ nm. Conversely, green and blue colors indicate the measured brightness at $\lambda = 557.7$ nm and $\lambda = 486.1$ nm, respectively.

the spectrally derived parameter values. **Figure 2** is an example of spectra of the $\lambda = 630.0$ nm thermospheric emission line, recorded by an all-sky-viewing Fabry-Perot hyperspectral imager.

Daytime Airglow Spectrometers

During the day, airglow emissions are seen from the ground superimposed upon a blue-sky background of scattered sunlight, which, for small wavelength intervals, exhibits approximately the same spectrum as direct sunlight. This atmospherically scattered sunlight is not only spectrally complex; it is also very much brighter than the airglow. For example, the left panel of **Figure 3** shows that the $\lambda = 630$ nm daytime airglow feature appears superimposed on a corresponding Fraunhofer absorption line, but with only about 1% to 2% of the brightness of the solar continuum.

It is possible to isolate the daytime airglow spectrum, by subtracting a suitably normalized version of the solar background spectrum (**Figure 3(b)**). However, this requires a spectrometer with a single passband and extremely high spectral resolution ($R \geq 200000R$ for the $\lambda = 630$ nm daytime airglow). These requirements can be met by a multiple-etalon Fabry-Perot spectrometer such as the one used to obtain **Figure 3** or, possibly, by a grating spectrometer operating in Echelle mode to achieve the maximum possible wavelength dispersion.

Commonly Observed Wavelengths

Airglow and auroral spectra are complex, exhibiting many discrete emission lines. **Table 1** shows some of those most commonly observed by airglow and auroral instruments.

Figure 2 Spectra of the atmospheric $\lambda = 630.0$ nm optical emission recorded by a ground-based all-sky-viewing Fabry–Perot hyperspectral imager. The circular region represents the instrument’s field of view in the sky. Signal processing in the instrument divides this field of view into 47 independent regions. Here, the regions are rendered using different colors, allowing the extent of each one to be discerned. The central region maps to viewing the sky in the zenith, whereas the outer regions map to viewing directions close to the horizon. An independent spectrum of the $\lambda = 630.0$ nm emission is measured from each region, spanning a wavelength interval of only ~ 10 pm. These measured spectra are depicted using small white crosses. The magenta curves depict numerically fitted model spectra, whereas the continuous white curves depict the spectra obtained by viewing a helium–neon laser. The increased width of the sky spectra compared with the laser spectra can be used estimate the temperature of the emitting atoms in the upper atmosphere.

Figure 3 (a) Spectra of sunlight and of daytime blue skylight spanning a wavelength interval of ~ 40 pm and centered near $\lambda = 630.0$ nm. The broad dip seen in both spectra is due to a Fraunhofer absorption line. The smaller hump in the sky spectrum roughly centered on channel 70 is due to daytime airglow. Note that the zero intensity level lies far below the bottom axis in this figure. (b) The spectrum of daytime airglow, obtained by subtracting the sun spectrum from the sky spectrum. The smooth curve superimposed upon the measured data is the result of fitting a numerical model spectrum.

Table 1 Spectral emission lines commonly observed by airglow or auroral optical instruments

Wavelength (nm)	Species	Height	Comments
557.7	O	97–140 km	97 km for airglow, higher for aurora
630.0	O	180–250 km	Airglow and aurora
427.8	N ₂	95–110 km	Aurora only
589.0/589.6	Na	90 km	Emitted by sodium atoms ablated from meteoric dust particles
840.0	OH	87 km	One of many OH lines
732.0	O ⁺	200–250 km	Useful for ion drift
486.1	H	100–120 km	Proton aurora

Viewing Locations

The vast majority of airglow instruments are ground-based, and offer long-duration measurements at minimum cost. However, ground-based observations are limited in several important ways, including the following:

- A ground-based site can view only a limited geographic region.
- The lower atmosphere is opaque to ultraviolet radiation at wavelengths shorter than ~ 300 nm, making airglow or aurora at these wavelengths unobservable from the ground;
- The upper atmosphere must be viewed through the troposphere, which is often cloudy and, when sunlit, appears much brighter than the airglow (due to scattered sunlight);
- It is difficult to recover an altitude profile of the emission intensity from ground-based viewing, particular for diffuse and featureless airglow layers.

For applications that must overcome one or more of these limitations, instruments can be flown (albeit at considerable expense) on balloons, aircraft, sounding rockets, low-orbiting satellites, or distantly orbiting satellites.

A trend since the early 1990s has been the use of computerized tomography to combine observations from several different viewing locations to recover the three-dimensional structure of airglow or auroral features. This method is an extension of ground-based triangulation that was originally used to determine the heights of atmospheric optical emission features.

Design Considerations for Airglow Instruments

General Characteristics

To facilitate discussion of some general principles, consider the ‘generic’ airglow instrument depicted in [Figure 4](#). All optical instruments must include at least one detector that records the light intensity incident upon it. The detector area may be divided into one or more independent elements, usually termed ‘pixels’. Prior to the 1960s, most optical detection was done with photographic film. Since that time various optoelectronic technologies have largely superseded photographic recording, except in specialist applications. Film continues to excel in applications requiring the combination of a large

Figure 4 A schematic depiction of a ‘generic’ airglow instrument observing the distant sky. This figure illustrates the detector, the entrance pupil, and the field of view in the sky.

sensitive area (more than ~ 1000 mm²) and a very large number of independent pixels (more than a few million).

Some combination of optical components is placed in front of the detector. Light enters this system through an aperture known as the entrance pupil. Note that the entrance pupil itself need not be a physical object. Frequently, it is merely a virtual image of some physical aperture that is located further back in the optical path.

The optical components relay light from the entrance pupil to the detector(s). Although [Figure 1](#) indicates that these components have formed a sharp image of the sky onto the detector, this need not be the case in general.

An instrument with a nonzero optical throughput must accept radiation over a nonzero range of incidence angles, for

both of the angular dimensions subtended by a distant scene (such as the atmospheric airglow viewed from the ground). The angular region accepted by the instrument is known as its field of view. The solid angle subtended by the field of view at the entrance pupil is usually denoted as Ω .

Light-Gathering Power

Nighttime airglow is extremely dim at visible wavelengths. The ground-level photon flux is comparable to that from a candle at ~ 100 m altitude. Thus, by far the major design issue for any airglow instrument is to achieve adequate sensitivity for the intended measurement.

The light-gathering power of any optical system is limited by a quantity known as its 'etendue', denoted by E . Physically, this is given by the product of the area of the entrance pupil, A , multiplied by the solid angle observed, Ω , i.e.

$$E = A\Omega$$

This fundamental limit determines the maximum number of photons that an instrument can collect per unit time. E is conserved within the optical path, which means that the etendue of a practical instrument is usually determined by limitations of optical components located somewhere in the optical path behind the entrance pupil. The dimensions of E are $(\text{length})^2 \times (\text{angle})^2$, and the conventional unit used is the square centimeter steradian.

Conventionally, the surface brightness of an extended airglow source is measured in units called Rayleighs. The number of photons an instrument with an etendue of $E \text{ cm}^2 \text{ sr}$, viewing a source with a uniform brightness of L Rayleighs throughout its field of view, will gather in one second is given by

$$\Phi = EL \frac{10^6}{4\pi}$$

(Inevitable optical losses within the instrument mean that substantially fewer of these photons will actually be detected.) Note that units of Rayleighs merely indicate a number flux of photons; no restriction is made regarding their spectral distribution. Thus, the brightness of an isolated narrowband spectral line emission can be measured directly in Rayleighs, provided that it is assumed that the photon flux is integrated over all wavelengths within the emission's spectral envelope. By contrast, the brightness of a broadband or continuum source, such as the daytime blue sky, must be specified in units of Rayleighs per unit wavelength interval.

As an example, assume that an instrument with a circular entrance pupil of 50 mm diameter and a circular 1° full-angle field of view is observing the entire spectral envelope of the $\lambda = 630$ nm airglow, which is emitting a typical midlatitude nighttime intensity of 50 Rayleighs. The solid angle viewed is

$$\begin{aligned}\Omega &\approx \frac{\pi\theta^2}{4} \\ &= \pi \times (1^\circ \times \pi/180)^2 / 4 \text{ sr}\end{aligned}$$

and the etendue is

$$E = \pi \times 2.5^2 \times \frac{\pi(1^\circ \times \pi/180)^2}{4} = 4.70 \times 10^{-3} \text{ cm}^2 \text{ sr}$$

The number of photons admitted to the instrument per second is then

$$\begin{aligned}4.70 \times 10^{-3} \text{ cm}^2 \text{ sr} \times 50 \times (10^6/4\pi) \text{ cm}^{-2} \text{ sr}^{-1} \text{ s}^{-1} \\ = 1.8 \times 10^5 \text{ s}^{-1}\end{aligned}$$

No matter what optical components are placed behind the entrance pupil, this is the maximum possible rate of photon detection.

Many airglow instruments apply optical components that disperse the incident radiation into multiple independent 'channels' – separated, for example, according to wavelength or viewing direction. While there are good reasons to do this, it must be understood that each individual channel only receives a corresponding fraction of the total incident photon flux. For example, if a square detector consisting of (say) 256×256 pixels is replaced by one of the same size, but divided into 512×512 pixels, then the modified instrument must observe for four times as long to achieve the same signal level in each pixel.

Optical Losses

No optical components are 100% efficient. Losses of at least a few percent occur at every optical surface owing to absorption, scattering, unwanted reflections, or imperfect geometric alignment. If there are components (such as filters) with limited spectral bandwidth, further losses may occur if these are poorly matched spectrally, either with each other or with the spectrum of the incident radiation. Finally, no detector can record 100% of the photons incident upon it. The fraction that are recorded (known as the 'quantum efficiency') varies between a few percent and $\sim 80\%$ for the types of detector typically used in airglow instruments. Taken together, these losses result usually in an actual rate of photon detection that is only a small fraction of the theoretical maximum based on the system etendue and the source brightness.

Calibration

Depending on the application, absolute calibration of the instrument's wavelength and/or intensity response may be required. Of these two, wavelength calibration is by far the easier, as emission lines from inexpensive spectral lamps provide highly precise and stable wavelength references.

Certain experiments (such as Doppler wind measurement) require wavelength measurements with extremely high precision. For example, the Doppler shift from a wind of 3 m s^{-1} corresponds to a wavelength change of only one part in 10^8 . Unfortunately, several of the airglow lines used for wind measurements are emitted by atomic transitions from long-lived metastable states. (Two examples of this are the $\lambda = 557.7$ nm and $\lambda = 630.0$ nm atomic oxygen lines, whose parent states have radiative lifetimes of ~ 0.7 and ~ 110 s respectively.) It is difficult to obtain a non-shifted wavelength reference for these emissions in the laboratory, because their parent states are quenched by collisions with container walls for any lamp of reasonable size. In the upper atmosphere, by contrast, there are no walls, and radiation from long-lived states is possible. Fortunately, it is usually possible to derive a zero-velocity wavelength reference from the data themselves.

One common method uses the (very reasonable) assumption that the long-term average vertical wind in the upper atmosphere should be close to zero.

Two related calibrations frequently required for spectrometry are the instrumental wavelength dispersion and the instrument's spectral response function. The dispersion can often be calculated *a priori* from the instrumental design parameters or, if a spectrum can be recorded over a sufficient wavelength range, from the positions of two or more calibration lines. The spectral response function can be obtained by observing a laboratory source known to emit a very narrow spectral feature. Suitable sources include lasers and certain unstructured spectral lines of high-mass atoms, such as the $\lambda = 546.1$ nm emission from mercury-198. If the spectral response is desired at some wavelength far removed from that available for calibration then instrumental design parameters must be used to calculate the required wavelength transformation.

Perhaps surprisingly, intensity calibrations are much more difficult. Instruments are calibrated with respect to secondary references, which are usually incandescent lamps that have themselves been calibrated in a national standards facility. An incandescent lamp approximates a point source, whereas for intensity calibration it is desirable to fill the instrument's field of view with a uniform brightness. Thus, in practice, the instrument is arranged to view lamp radiation scattered off an extended Lambertian screen. Applying calibration data for both the lamp and screen allows calculation of the screen brightness in Rayleighs per unit wavelength. When an instrument views the screen then the resulting signal represents the integral under the product of the screen's emission spectrum multiplied by the instrument's spectral response function. This integral has units of Rayleighs; it is related to the total screen brightness within the instrumental passband by a scalar calibration constant. Thus, provided the instrument's spectral response function is known, this procedure assigns the observed response to a calculated number of Rayleighs, which is the desired intensity calibration. Of course, the procedure must be repeated for all wavelengths of interest. It should also be repeated over a range of screen brightness, as many instruments have a nonlinear intensity response.

Signal Requirements

In an analogy to the need to observe a nonzero solid angle, every measurement must be made by integrating the incident photon flux for a nonzero interval of time. A primary figure of merit for any optical instrument used in low-light applications is the exposure time required per measurement – the shorter the time, the better the performance. This time is limited ultimately by the Poisson statistics associated with counting discrete photons. That is, the number of photon detections, N , needed to measure an intensity to a precision of p percent must satisfy

$$p \leq \frac{100\sqrt{N}}{N} \quad \text{or} \quad N \geq \left(\frac{100}{p}\right)^2$$

For example, if we wanted to measure intensity to a precision of 2%, we would need to count 50^2 photons. If the instrument that we considered earlier had an overall detection efficiency of

10%, then it would require an integration time of $50^2/(0.1 \times 18 \text{ kHz})$, or 1.4 s, to achieve this precision for the assumed 50 Rayleigh source.

Frequently, there are other sources of intensity uncertainty beyond those arising solely from the Poisson statistics of counting the signal photons. A widely applicable expression for the actual measurement uncertainty after t seconds of photon counting is

$$\sigma_N^2 = st + Bt + R^2$$

where s is the detection rate of signal photons, B is the occurrence rate of 'background' counts, and R is a one-time noise penalty incurred in certain detectors during read-out. Background counts can arise from stray light entering the instrument, from electronic noise within the detector, or from both. In this case, the integration time required to measure the signal intensity to a precision of p percent must satisfy the relation that

$$\frac{100\sqrt{st + Bt + R^2}}{st} \leq p$$

so

$$t \geq 100 \times \frac{50s + 50B + \sqrt{(2500s^2 + 5000sB + 2500B^2 + p^2s^2R^2)}}{p^2s^2}$$

Applying this to the earlier example, but now with $B = 500$ Hz and $R = 20$ counts, would increase the required integration time from 1.4 to 1.9 s. Clearly, longer integration times are needed as additional sources of noise become significant. Setting both $B = 0$ and $R = 0$, and substituting $st = N$, shows that this expression then reduces to that for Poisson statistics of the signal photons alone.

The Dimension Problem

Typical optical detectors resolve at most two dimensions at once (by recording an image). However, many airglow applications require resolution over more dimensions than this. For example, the Doppler width of an airglow emission line can be used to infer atmospheric temperature. A map of Doppler linewidths across a wide field of view in the sky would yield a corresponding map of atmospheric temperature. However, to achieve this in practice requires recording a complete line spectrum for each pixel in the sky image. Observing the time evolution of a temperature map would require resolution in four dimensions – time, wavelength, and two angular dimensions across the sky.

It is often possible to map the detector's imaging dimensions onto any two of the desired measurement dimensions. However, to resolve more than two dimensions we must use some form of multiplexing, either in time or else across the detector spatially.

Some imaging devices can actually resolve a third dimension, at least crudely. Color film is an example of this, as are new superconducting tunnel junction devices that can resolve wavelength by counting the number of Cooper pairs that are dissociated per incident photon.

Synopsis

Continuous measurements of ozone have been made for several decades, with the longest record starting in 1926. While the longest records are from ground-based stations, global coverage was only achieved in 1979 with instruments carried on satellites. Together these show the following general features. In polar regions, severe ozone depletion occurs over Antarctica each Austral spring (the Antarctic ozone hole), while only in some years do large ozone losses occur over the Arctic in Boreal spring. Smaller long-term decreases over the midlatitudes in both hemispheres, with the larger losses occurring in the Southern Hemisphere. There are no significant ozone trends over the tropics. Changes in chemical composition, particularly chlorine and bromine, and changes in atmospheric dynamics have influenced ozone. It is important to distinguish between these and other factors in order to assess the effect of the international phasing out of the emissions of ozone-depleting substances and the possible influence of climate change on stratospheric ozone and UV radiation.

Background

Accurate determination of the magnitude and nature of trends in ozone is needed if the relative contributions of the various possible causes of decadal changes in ozone are to be distinguished. The Antarctic ozone hole is a good example where ozone measurements provided tight constraints on the possible causes of the rapid springtime depletion. High-quality measurements of the total ozone column (integrated from the ground to the top of the atmosphere) since the 1950s provided an excellent climatology, which showed that the decline first observable in the late 1970s was a new phenomenon and not part of the natural variability. These same measurements showed that total ozone dropped rapidly from the end of August and that extensive loss did not take place in the polar night, but only upon the return of sunlight. Measurements of the vertical distribution of ozone soon confirmed the latter point and, more importantly, showed that the loss occurred in the lower stratosphere, principally at altitudes between 15 and

20 km. By early October, the atmosphere between 14 and 21 km altitude in the core of the vortex is practically devoid of ozone. The average total ozone columns in Antarctic spring (September to November) in the 1990s were about 60% lower than those in the 1960s. During the 1990s and 2000s, the Antarctic ozone hole of late winter and spring continued unabated, with a single exception in 2002. That year apart the final warming of the vortex, which effectively marks the end of the ozone hole, has taken place a month or so later in the last two decades than in the 1960s to the 1980s. These observations tightly constrain possible explanations, especially when allied with the chemical and aerosol measurements made since the 1970s.

There is no other region where available ozone measurements provide such tight constraints. While this is partly due to the large size of the ozone loss over Antarctica that dwarfs the uncertainties in the ozone measurements and partly due to the relative homogeneity inside the Antarctic vortex, it is also testament to the perseverance of the people who made the

measurements in such an adverse environment. A record of similarly high quality and duration is not available for most of the globe, and our knowledge of global ozone trends is limited by the length and quality of the available ozone record. This limitation is compounded by the smaller magnitude of the trends outside Antarctica. Reviews of the understanding of global ozone trends are presented in the series of the World Meteorological Organization (WMO) assessments.

Long-Term Ozone Measurements

The importance of ozone lies principally in its ability to absorb UV-B radiation (light with wavelengths <310 nm). Because of this, little UV-B radiation penetrates to the Earth's surface. A decrease in the total amount of ozone in the atmosphere (most of which is in the stratosphere) would lead to higher UV-B levels at the Earth's surface than occurs naturally and so lead to damage in life-forms because they are not adapted to it. This same property (absorption of UV radiation) can be used to measure atmospheric ozone, with more ozone leading to greater absorption of UV and less ozone leading to less absorption. Most of the measurements referred to here are based on this basic principle. Applying it in practice is not straightforward, as proper account must be taken of factors such as atmospheric particles and sulfur dioxide, which also interact with UV radiation.

Our picture of the multidecadal variations in total ozone comes from the ground-based network, principally Dobson spectrophotometers, which was mainly in the northern midlatitudes in the early years. Reliable records in this region have been available from several locations since the early 1960s. The quality of the global record is patchy, but it has been greatly improved over the last 30 years with the introduction of internationally agreed operating procedures and quality assessment. The longest continuous record of measurements is from Arosa in Switzerland, where measurements of ozone have been made since the 1920s. [Figure 1](#) shows the measurements from Arosa since the 1920s.

It is now over 30 years since the Nimbus 7 satellite was launched which included the TOMS and SBUV sensors in its

payload. The two instruments worked for unexpectedly long times until 1993 and 1990, respectively. Subsequent versions of both sensor types have been flown, and it is possible to combine records from the different instruments, provided great care is taken with their absolute calibrations. In practice, the only independent means of assessing this is by comparison with the ground-based stations, a process that inevitably reduces the true independence of the ground and satellite systems. Other satellite instrument series have been operational since the 1990s. It is important that the various satellite systems are used in complementary ways that serve to increase the quality of the world's ozone observing system. Experience has shown the great value of the well-run, closely calibrated network of ground-based instruments that operate within WMO's Global Ozone Observing System ([Figure 2](#)) and the need to continue this in future. The average global ozone distribution is also shown, with high values at higher latitudes.

The limits on statistical significance imposed by natural variability and particularly by uncertainty in instrumental calibration do not necessarily equate with scientific importance. Two particular instances stand out – ozone over the tropics where a small change in ozone could have large radiative and climatic impact, and ozone in the lower stratosphere which is hard to measure with good precision and accuracy on the global scale.

Ozone Changes

Recent analyses of total ozone data confirm the now familiar features of the stratospheric ozone depletion that has occurred since the 1970s. At midlatitudes in the Northern Hemisphere, there has been a statistically significant decline in the total ozone in all seasons ([Figures 1](#) and [3](#)) with larger reductions in winter and spring than in summer and autumn. The loss of ozone at southern midlatitudes is also statistically significant throughout the year, albeit with a smaller seasonal variation. No statistically significant trends in total ozone have been observed in the tropics. These features can all be clearly seen in [Figure 3](#) that shows five different sets of ozone measurements.

Figure 1 Total ozone measurements at Arosa, Switzerland, from 1926 to 2011. The thin solid line and dots show the annual averages, with a dotted line prior to 1932 to indicate the large fractions of missing data at that time. The thicker line is the 11-year running mean. The measurements are performed by MeteoSwiss. Figure courtesy of H. Rieder.

Figure 2 The average global ozone distribution with low values in the tropics and higher values at higher latitudes. The diamonds illustrate the ground-based stations where ozone measurements are made within the World Meteorological Global Atmospheric Watch (WMO-GAW) network. Courtesy of WMO.

Figure 3 Annual mean area-weighted total ozone deviations from the 1964–80 means for five latitude bands, estimated from different global data sets. Deviations are expressed as percentages of the ground-based time average for the period 1964–80. Figure from Chapter 2 of WMO Scientific Assessment of Ozone Depletion: 2010. World Meteorological Organisation Global Ozone Research and Monitoring Project, Report No. 52, Geneva, Switzerland, 2011.

These deseasonalized time series show remarkable consistency with excellent stability and agreement to about $\pm 1\%$.

The top two plots (60°S – 60°N and 90°S – 90°N) are different measures of the global total ozone amount: both are used because there are only a few measurements in polar regions and these are overwhelmingly made in summer when sunlight is present. Both show a decrease in total ozone, starting around 1980. The largest decrease (4–6%) occurred in the early to mid-1990s, which is ascribed to the presence of large amounts of volcanic aerosol following the eruption of Mt Pinatubo in 1991. However, since the late 1990s (when the effects of Mt Pinatubo had largely dissipated), the global total ozone amount has not changed much, being 2–4% below the pre-1980 levels.

A similar and somewhat magnified behavior is observed in the record from northern midlatitudes (35°N – 60°N) where the influence of Mt Pinatubo is seen most strongly. However, there is a marked contrast with the behavior observed over southern midlatitudes (35°S – 60°S) where there is no increase in the years following the Mt Pinatubo eruption. In recent years, total ozone values in northern and southern midlatitudes have stabilized at respectively about 3.5 and 6% lower than the 1964–80 average. In both hemispheres, there is little sign of increase in recent years.

No statistically significant trends in total ozone have been found in the tropics (25°S – 25°N), though there are indications of a small decrease in the 1990s around the time of Mt Pinatubo.

When looking at changes of a few percent that result from several causes, there is a danger of over-interpreting changes of 1% – after all this is the estimated stability of the observational network for total ozone. It is clear, given the sizes of the changes and the measurement uncertainty, that care must be taken in discussions of the possible ‘recovery’ of the ozone layer. For example, when interpreting the ozone record, the assumptions underlying the analysis must be valid. The statistical models used to calculate ozone trends attempt to account for a number of sources of variations in ozone. The standard approach is to describe the effects of natural phenomena such as the quasi-biennial oscillation (QBO) and the 11-year solar cycle by assuming a linear relation between the strength of these phenomena and total ozone. The ozone trends used to be assumed to be linear, but this is no longer the case now that the concentration of ozone-depleting substances (ODSs) is decreasing. The details of the statistical analysis would be of solely academic interest if the relationship of total ozone with the various influences was well established, but in practice this is not the case. The impact of volcanic eruptions is particularly hard to assess in this regard as their impact depends on location, strength, and timing as well as the level of ODS in the atmosphere.

Having said all that, there is clearly considerable scientific and public interest in being able to identify a recovery in ozone as a result of the ODS reductions occurring after the implementation of the Montreal Protocol. One of the places where this signal might be most easily discernible is the upper stratosphere, where (1) the effects of the ODS-related chemical ozone loss are relatively large and well understood; and (2) the measurements are of high quality. Figure 4 shows a composite of ground-based and satellite measurements taken at five

Figure 4 Ozone anomalies at altitudes of 35–45 km from 1979 to mid-2012 for eight data sets at five ground-based stations in the Network for the Detection of Atmospheric Composition Change. The gray underlay shows the range for an ensemble of climate-chemistry models. The thin black lines at the top and bottom show negative 10 hPa zonal wind at the equator as a proxy for the quasi-biennial oscillation, and 10.7 cm solar flux as a proxy for the 11-year solar cycle, respectively. The thin magenta line near the bottom shows inverted effective stratospheric chlorine (ESC) as a proxy for ozone destruction by chlorine. Updated from Chapter 2 of WMO Scientific Assessment of Ozone Depletion: 2010. World Meteorological Organisation Global Ozone Research and Monitoring Project, Report No. 52, Geneva, Switzerland, 2011. Figure courtesy of W. Steinbrecht.

ground stations in northern midlatitudes, tropical latitudes, and southern midlatitudes. The most obvious feature is the upper stratospheric ozone decline from 1980 to the mid-1990s. It is also clear that decline has stopped and ozone has stabilized since 1995–96. However, no statistically significant trend is found in this period and it is not yet possible to attribute any change in ozone trends to changes in ODS.

Large changes were also seen at lower altitudes (between 10 and 25 km) in the extratropics with no significant change at 30 km. It is hard to assess the recent changes at these altitudes, partly because there are large natural variations that have strong regional dependencies and partly because the available measurements do not give a coherent, long-term picture. This is a concern because changes of ozone in the tropical lower stratosphere and upper troposphere are of the great potential importance to climate change.

Finally, it is interesting to compare what happens over the Arctic with the dramatic changes that have occurred over Antarctica – and the picture is certainly more complex.

The observed ozone losses in the Arctic vary a great deal from winter to winter, with large losses in cold winters when the processes leading to chemical ozone loss are favored. Large ozone losses (20–30% in the column and 40–70% at altitudes around 18 km) caused by chemistry have occurred in the colder winters. Most notable was the ozone loss in spring 2011, which was the closest yet to an Antarctic ozone hole. Here, over 80% of the ozone between 18 and 20 km was destroyed, and the column ozone loss was similar to that which occurs in the Antarctic. Important differences remain, including the facts that ozone amounts in the Arctic are naturally higher than in the Antarctic (so that a greater loss is required to reach the same level) and the Arctic is not cold every year so that such large losses will remain exceptional.

Discussion

It is clear that chlorine and bromine compounds resulting from ODS breakdown lead to ozone depletion, but it is also clear that they do not account quantitatively for all of the observed trends. There is no doubt that rapid chemical ozone loss occurs over the Antarctic and Arctic in winter/spring. The signal is large and a whole host of chemical measurements allow unambiguous identification of perturbed chlorine and bromine chemistry as the cause. There is equally no doubt that the ozone-depleted air is subsequently mixed over larger areas and leads to reduced ozone amounts over midlatitudes.

Other factors are also involved. Statistical analyses of total ozone trends routinely include terms to describe the influence of the solar cycle and the QBO on total ozone. With over 30 years of global satellite data and over 50 years of ground-based observations – i.e., longer than the periods of these or other natural phenomena that could affect ozone – any total ozone changes resulting from the increase in ODS are reasonably robust to possible errors in the description of these phenomena. However, identification of any recovery (based on 10–15 years of measurements since the ODS maximum) still requires correct attribution of these factors.

In order to separate the various influences, close attention is paid to examining the time series of ozone measurements in order to extract information on possible mechanisms from the observed interannual variations. For example, 2D and particularly 3D models of stratospheric chemistry and dynamics have been used to investigate this, with their simulations including the effect of observed aerosol amounts on the trends calculated for the chlorine and bromine changes and observed changes in stratospheric transport. The calculated ozone changes following the major volcanic eruptions in the 1980s and the 1990s are consistent with variations in the observed total ozone record. In particular, a difference in behavior is found in the northern and southern midlatitudes. The reasons for this difference include a greater loss in the Antarctic that dilutes the ozone amount more in southern midlatitudes that does the smaller loss in the Arctic; a greater effect of Mt Pinatubo on the Northern Hemisphere; and a greater decadal variability in the dynamic influence on ozone in the Northern Hemisphere.

Long-term changes in the circulation of the atmosphere connected with climate change are and will be causing long-

term changes in total ozone. A number of changes are already occurring that will have important consequences for the stratosphere and stratospheric ozone. For example, changes in temperature have been observed, with episodic jumps associated with volcanic eruptions superimposed on a long-term cooling trend; an increase in tropopause height (and decrease in tropopause pressure) has been observed globally which at a simple level means that the stratosphere is getting smaller; and there is a widening of the tropical belt. These changes are all associated with climate change and are all having important, though incompletely understood consequences for stratospheric ozone amounts and distribution.

So, looking to the future, total ozone will be subjected to chemical and dynamical influences. The major chemical influence is from the declining levels of ODS as a result of the success of the implementation of the Montreal Protocol. The secondary chemical influence from is the likely changes in the chemically important, greenhouse gases, methane (CH_4) and nitrous oxide (N_2O): the main uncertainty in predicting these changes arises from uncertainties in their future emissions. However, the dynamical influences associated with climate change could be greater and are currently known with far less certainty.

Unambiguous identification of the effect of the Montreal Protocol on ozone observations has been a ‘holy grail’ for a few years as there is real value to providing definitive proof of a success of environmental legislation. However, with so many competing influences on ozone to account for, it is extremely hard to achieve. Scientists have looked at regions where the influence of ODS-related chemistry is particularly strong such as the upper stratosphere (Figure 4) and the Antarctic ozone hole. To date, they have not succeeded. In the upper stratosphere, for example, the observed cooling affects the speed of the ozone chemistry in such a way that more ozone is calculated to be present when the ODS are gone than before they were introduced. The sustained increase in N_2O concentration is perturbing the chemistry further. The Antarctic may be a better place to look, but even there it is likely to be decades before an ozone recovery can be rigorously identified.

Ozone as a UV Filter

Synopsis

Atmospheric ozone absorbs incoming solar radiation, where the attenuation is greatest in the ultraviolet part of the spectrum. The absorbing properties of ozone are expressed in values of the absorption cross section, and these provide the basis for computing the transmission of the Earth's atmosphere as a function of wavelength. As a consequence of attenuation by ozone, essentially no solar energy reaches the Earth's surface at wavelengths shorter than 295–300 nm, while ground-level radiation at wavelengths between 300 and 315 nm is sensitive to the ozone content of the atmosphere.

Introduction

Historically, interest in atmospheric ozone (O_3) emphasized the molecule's role in absorbing incoming ultraviolet sunlight. As a consequence of the attenuation provided by ozone, little or no solar radiation reaches the Earth's surface at ultraviolet wavelengths between approximately 200 and 300 nm. At shorter wavelengths, from 200 to 240 nm, absorption by the diatomic oxygen molecule (O_2) also takes place, while at wavelengths longer than 300 nm the attenuation provided by ozone weakens, although absorption occurs at wavelengths that extend through the visible region.

The Sun emits radiant energy over a broad range of the electromagnetic spectrum, while the human eye responds only to the portion that lies at visible wavelengths from 400 to 780 nm. Approximately 46% of the Sun's total energy lies in the visible. Another 46% exists in the infrared at wavelengths longer than 780 nm, while only 8% of the Sun's radiant energy exists at wavelengths shorter than 400 nm in the ultraviolet. Despite this relatively modest absolute energy, the ultraviolet is responsible for driving much of the chemistry of the Earth's atmosphere as well as for degradation of artificial materials and effects on living things at the Earth's surface.

In the late nineteenth century, scientists believed that the Sun emitted radiation in the ultraviolet, although the human eye does not respond to energy at these wavelengths. Measurements designed to detect ultraviolet radiation revealed the expected levels of sunlight reaching the ground at wavelengths from approximately 315 to 400 nm, a spectral region called the UV-A. However, at shorter wavelengths the instruments observed an extremely steep decline in energy. This spectral region, which is marked by a precipitous drop in ground-level radiation as wavelength decreases, is known as the UV-B. In standard usage the UV-B encompasses wavelengths from 280 to 315 nm, although for practical purposes, no solar energy reaches the Earth's surface at wavelengths shorter than 295–300 nm.

The scarcity of UV-B radiation at the ground presented a dilemma for scientists who first observed this behavior. The steep drop in radiant energy with decreasing wavelength was not consistent with the spectrum of radiation emitted by hot objects observed in the laboratory. The visible radiation received from the Sun suggested an object whose absolute temperature was in the vicinity of 5700–5800 K, but a radiator at this temperature should have a larger emission in the UV-B than was

present in sunlight at the Earth's surface. The resolution to the problem was that the Sun did indeed emit energy in the UV-B portion of the spectrum, but somewhere between the Sun and the surface of the Earth much of this energy was absorbed.

In 1881 the English chemist William Hartley created ozone in the laboratory by shooting electrical sparks through a container of dry air. He then directed ultraviolet light from a lamp through this ozone. He observed that the ozone absorbed the very same ultraviolet wavelengths that were absent from sunlight at the ground. Both the spontaneous formation of ozone in the laboratory and the selective wavelength-dependent absorption of ultraviolet radiation by this ozone led Hartley to suggest that ozone formed in the Earth's atmosphere, and absorption by ozone was responsible for the near absence of the UV-B component of sunlight at the ground. Subsequent studies in the early twentieth century demonstrated that atmospheric ozone resided somewhere above the tops of tall mountains, and optical methods eventually confirmed that most of the ozone exists in the stratosphere, between 10 and 50 km in altitude.

Figure 1 illustrates the ground-level solar ultraviolet spectral irradiance over the wavelength range 290–340 nm. Irradiance

Figure 1 Ultraviolet solar irradiance striking a horizontal surface at the ground over the wavelength range 290–340 nm. The values, based on model calculations, refer to latitude 40° N at solar noon in mid-July under clear skies.

is defined as the energy per unit time that strikes a unit horizontal area per unit wavelength interval, where the typical unit is $\text{W m}^{-2} \text{ nm}^{-1}$. These results come from a numerical model that treats absorption and scattering of sunlight as a function of wavelength as the solar beam passes through the atmosphere. The values in Figure 1 refer to latitude 40° N in mid-July at noon under clear skies. In the UV-B the solar irradiance at the ground decreases by two orders of magnitude as wavelength declines from 315 to 297–298 nm. This behavior results from absorption by atmospheric ozone.

Molecular-Scale Interactions

The absorption of solar UV-B light is a manifestation of processes that occur on the molecular scale. An ozone molecule consists of three oxygen atoms held together by two bonds, which arise from the sharing of electrons. The length of each bond is 0.126 nm, indicating the characteristic dimension of the molecule. Ultraviolet sunlight interacts with the molecule by breaking one of the bonds leading to photodissociation, written as $\text{O}_3 + h\nu \rightarrow \text{O}_2 + \text{O}$. In this process a quantum of light, denoted by $h\nu$, is destroyed and the energy goes into breaking one of the two bonds in the original molecule.

To describe a photodissociation, it is convenient to view a beam of sunlight as if it consists of a stream of massless particle-like entities called photons. The energy of one photon is $h\nu$, where ν is the frequency of the light and h is the Planck's constant. Alternatively, the energy of a photon is hc/λ , where c is the speed of light and λ is the wavelength. To dissociate an ozone molecule, the energy of the photon must exceed a specific minimum amount, called the binding energy ozone, which is determined by the strength of the molecular bond to be broken. There is a one-to-one correspondence between photons absorbed and ozone molecules dissociated; that is, absorption of one photon leads to the dissociation of one ozone molecule. In the process, the photon is annihilated, and its energy is expended in breaking one of the bonds in the ozone molecule. The binding energy of the molecule defines the maximum wavelength of light that is capable of causing photodissociation, called the dissociation wavelength. In the case of ozone, the dissociation wavelength lies in the infrared part of the spectrum, and any photon whose energy exceeds the binding energy can break ozone into O_2 and O . Any excess photon energy appears in kinetic energy or in excited states of the products. In practice, the photodissociation of ozone becomes efficient only for photons that are much more energetic than the binding energy and that correspond to light in the ultraviolet part of the electromagnetic spectrum.

The absorption cross section of ozone describes the interaction of radiation with the molecule and the wavelength-dependent values reflect the strength of absorption across the spectrum. Laboratory measurements are able to determine the magnitude of the cross section, and these empirical values provide a means to compute the transmission of the atmosphere throughout the ultraviolet spectral region. Figure 2 depicts a beam of light incident on a layer of ozone at an angle θ to the vertical. Let $L_0(\lambda)$ be the incident radiance at wavelength λ , and $L_T(\lambda)$ be the transmitted radiance that exits from the bottom of the slab. Radiance has a unidirectional

Figure 2 Attenuation experienced by a beam of ultraviolet light in passing through a layer of ozone.

character, whereas irradiance, as in Figure 1, sums over energy propagating downward from all locations in the sky. The layer in Figure 2 has a thickness Δz in centimeters and contains ozone in the amount n_{oz} molecules per cubic centimeter. When absorption is the only process operating, the relationship between the transmitted and incident radiance is given by Beer's law (eqn [1]).

$$L_T(\lambda) = L_0(\lambda) \exp[-\sigma(\lambda) n_{\text{oz}} \Delta z / \cos \theta] \quad [1]$$

The quantity $n_{\text{oz}} \Delta z / \cos \theta$ specifies the number of ozone molecules per unit area measured along the slant path taken by the beam of light through the layer. Equation [1] is essentially a definition of the absorption cross section of ozone, $\sigma(\lambda)$, whose dimension is area, typically expressed in square centimeters. The cross section describes the strength of absorption per ozone molecule as a function of wavelength. If λ_D is the dissociation wavelength, then $\sigma(\lambda) = 0$ for all $\lambda > \lambda_D$, and at these wavelengths a beam of light is unaltered in passing through a layer of ozone. For $\lambda < \lambda_D$ the degree of attenuation depends on the magnitude of the absorption cross section, which varies dramatically with wavelength.

In principle, it is possible to compute the absorption cross section, given a complete knowledge of the molecular structure of ozone, although in practice this is neither practical nor feasible. Instead, applications in atmospheric science make use of absorption cross sections determined empirically. Here a monochromatic light source illuminates a laboratory chamber that contains a known concentration of ozone. Then from measurements of the radiance incident on and transmitted through the chamber, eqn [1] allows deducing the cross section at the wavelength of incident light. By varying the wavelength, one can infer values of the absorption cross section over the entire ultraviolet spectral region of interest in atmospheric applications.

Figure 3 depicts the absorption cross section of ozone measured over the wavelength range 200–340 nm, encompassing the UV-C, defined as wavelengths less than 280 nm, the UV-B, and the shortest wavelengths of the UV-A. The cross section in the 315–340 nm portion of the UV-A is very small compared to that in the UV-B, and a dependence on temperature is apparent. At wavelengths longer than 340 nm the attenuation provided by ozone is negligible, although dissociation is energetically possible throughout the remainder of the ultraviolet and visible portions of the spectrum. The

Figure 3 The absorption cross section of ozone and of molecular oxygen over the wavelength range 200–340 nm. The vertical scale on the left applies to ozone and that on the right to molecular oxygen.

wavelengths shown in [Figure 1](#), 290–340 nm, overlap the longer wavelengths in [Figure 3](#). A comparison of the two figures shows that the steep increase in ultraviolet irradiance with wavelength over this spectral range coincides with, and is a consequence of, the dramatic decrease in the absorption cross section of ozone as wavelength increases.

[Figure 3](#) shows a peak in the absorption cross section of ozone near 250 nm, with a sharp decline toward both longer and shorter wavelengths. Based solely on this behavior, one would expect to observe sunlight reaching the Earth's surface near 200–210 nm, since the cross section at these wavelengths is close to that at 300 nm. In fact, no solar radiation survives passage through the atmosphere at 200–210 nm because at wavelengths shorter than 240 nm molecular oxygen begins to absorb, and the photodissociation $\text{O}_2 + h\nu \rightarrow \text{O} + \text{O}$ occurs. Although the absorption cross section of O_2 , also shown in [Figure 3](#), is extremely small, a factor of one hundred thousand to one million less than that for ozone (see the right-hand scale for O_2), the atmosphere contains a very large amount of O_2 . The consequence of the combined absorption by O_2 and O_3 is that incoming sunlight over the entire UV-C is removed at altitudes far above the ground. The absorption by O_2 in photodissociation becomes stronger as wavelength decreases below 200 nm, and at much shorter wavelengths, less than 100 nm, absorptions by molecular nitrogen (N_2) and O_2 lead to ionization in the Earth's atmosphere at altitudes greater than 100 km. All of the above processes combined ensure that the surface of the Earth is totally shielded from the highest-energy photons in the solar spectrum.

Transfer of Solar Radiation through the Atmosphere

The transfer of UV-B and UV-A sunlight through the atmosphere is more complicated than depicted in [Figure 2](#) and [eqn \[1\]](#) because absorption by ozone is not the only process that alters the incoming solar beam. In passing through an atmospheric layer, incident light is both partially absorbed and also scattered. Scattering refers to a change in direction of propagation, with no change in the amount of energy

contained in the radiation field. Most atmospheric molecular scattering is by the major gases, N_2 and O_2 , since they are vastly more abundant than ozone. In addition, the atmosphere contains suspended small particles, especially in the lowest several kilometers of altitude, and these are important in scattering radiation.

At the top of the atmosphere, solar radiation at the wavelengths absorbed by ozone is incident as a direct beam coming from one specific direction in space. As this beam propagates downward, it is attenuated to an extent determined by the cross section of ozone at the wavelength considered, by the abundance of ozone molecules, and by scattering. But rather than destroying radiant energy, scattering redirects the sunlight into all possible angles over the upper and lower hemispheres. The area of physics known as radiative transfer develops the concepts and mathematical methods needed to compute the attenuated direct solar radiation and the scattered radiation moving in any direction at each altitude throughout the atmosphere as well as at the ground.

Scattering of radiation by objects much smaller than the wavelength of light, where molecules are prime examples, is called Rayleigh scattering, named after Lord Rayleigh who studied the process in detail. The attenuation of a direct beam of sunlight by Rayleigh scattering is described by an equation analogous to Beer's law ([eqn \[1\]](#)). In this case, the cross section for scattering is inversely proportional to wavelength raised to the fourth power ($1/\lambda^4$), and the appropriate number density is the total number of atmospheric molecules per unit volume in the layer. However, as the direct beam is attenuated, a scattered radiation field, with components propagating in all directions, is created. Rayleigh scattering explains the blue color of the sky on a clear day, since the shortest visible wavelengths, in the blue and violet spectral regions, scatter more efficiently than do longer wavelengths, in the yellow or red. The strong inverse wavelength dependence of the Rayleigh scattering cross section implies that ultraviolet radiation is scattered even more strongly than visible light. As a consequence, on a clear day much of the ultraviolet sunlight received at the ground is in the form of scattered radiation from the entire upper hemisphere as opposed to being concentrated in the direct beam from the Sun. Scattering by particles and liquid droplets acts in a way similar to that by molecules except that the wavelength dependence is much weaker than in the Rayleigh case. When particles and droplets are abundant, the sky takes on a whitish color, an indication that all wavelengths in sunlight are scattering with roughly equal efficiency.

Atmospheric scattering alters the amount of solar ultraviolet energy absorbed by ozone. This can be deduced from [Figure 2](#) and [eqn \[1\]](#). The attenuation of a beam of light depends on the ozone content of the layer in [Figure 2](#) and on the angle θ at which the radiation is incident. In the absence of scattering, all of the radiant energy would be concentrated at the single angle θ defined by the location of the Sun in the sky. With scattering, however, radiation impinges on a layer from all directions. From [eqn \[1\]](#), the attenuation by ozone is different for each value of θ . As a result, calculations of solar ultraviolet irradiance at the Earth's surface must treat the coupled actions of absorption and scattering at all altitudes throughout the atmosphere.

Although models that treat the transfer of ultraviolet sunlight through the atmosphere must include the complications identified above, eqn [1] still identifies the major variables that determine the solar irradiance at the Earth's surface. When applied to the atmosphere, θ in Figure 2 is the solar zenith angle, defined as the angle between the instantaneous position of the Sun and the local vertical. As the Earth rotates, the solar zenith angle at any location varies from 90° at sunrise to a minimum value at midday, called solar noon, and back to 90° at sunset. The apparent motion of the Sun relative to a point fixed on the Earth's surface is accompanied by a changing path length taken by solar radiation through the atmospheric ozone layer. The minimum path length and maximum UV-B irradiance at the ground occur at solar noon. An increase in the solar zenith angle, as occurs in the hours after solar noon, is accompanied by an increase in absorption by ozone and a decrease in ground-level UV-B irradiance. In addition to the changing magnitude of absorption, simple geometrical factors are significant as well. A fixed amount of solar energy is spread over a larger horizontal area at the Earth's surface as the angle of incidence, θ , increases. This leads to a decline in the energy received per unit horizontal area irrespective of absorption by ozone.

The dependence of solar zenith angle on latitude, season, and local time leads to large systematic variations in solar ultraviolet irradiance at the ground. Figure 4 illustrates the behavior of irradiance at several wavelengths in the UV-B and UV-A as functions of solar time during a clear afternoon at latitude 40° N in July, where 12:00 denotes solar noon, the time of minimum solar zenith angle. The irradiance at all wavelengths declines rapidly as the Sun gets closer to the horizon. At 340 nm, the irradiance is almost independent of the ozone amount, and the value at noon exceeds that at 17:00 h by a factor of three. This variation arises from increased atmospheric backscattering as the solar zenith angle increases acting in combination with the geometrical effect noted above. As wavelength decreases, absorption by atmospheric ozone becomes increasingly important and leads to a more pronounced dependence of irradiance

on solar zenith angle. At a wavelength of 305 nm, the noontime irradiance exceeds that at 17:00 h by a factor of 19, and at 300 nm this factor increases to 119.

Changes in Atmospheric Ozone Amounts and Ultraviolet Radiation

Concerns over depletion of the ozone layer arose in the 1970s, when scientists realized that chemicals released by various anthropogenic activities could lead to a slow decline in ozone amounts in the stratosphere. The importance of this depletion arose from ozone's role as an absorber of biologically damaging ultraviolet sunlight. Exposure to radiation in the UV-B, and to a lesser extent in the UV-A, is responsible for a variety of negative effects, including certain types of skin cancers, cataracts, and inhibition of plant development. Equation [1] implies that a decline in the number of ozone molecules in a column of the atmosphere would be accompanied by an increase in solar ultraviolet irradiance reaching the Earth's surface. If decreases in the ozone abundance continued over a period of decades, one would expect an increase in the incidence of the biological effects identified above. The relationship between ultraviolet radiation exposure and a specific biological response can be exceedingly complex and is often poorly understood on a quantitative basis. However, the increase in ground-level ultraviolet irradiance associated with a known change in atmospheric ozone content is straightforward to predict.

Figure 5 presents the changes in ultraviolet spectral irradiance reaching the ground for -10 and $+10\%$ changes in the column ozone amount. The vertical scale is the ratio of irradiance computed for an altered ozone amount to that for the unperturbed amount, where the reference state is 40° N latitude at noon in mid-July as shown in Figure 1. The wavelength scale extends from 290 nm, where negligible radiation reaches the Earth's surface, to 340 nm, where absorption by ozone is extremely weak. As wavelength decreases, the sensitivity of

Figure 4 Variation of ground-level solar ultraviolet irradiance at various wavelengths with solar time during an afternoon for latitude 40° N in mid-July under clear skies.

Figure 5 Sensitivity of ground-level ultraviolet irradiance to changes in the column ozone abundance of $+10$ and -10% about the unperturbed amount for latitude 40° N at noon in mid-July.

ground-level radiation to changes in the ozone amount increases rapidly. This type of behavior is qualitatively consistent with eqn [1] combined with the wavelength dependence of the absorption cross section in Figure 3, although realistic quantitative results must include the effects of scattering.

At the short-wavelength end of the UV-A, near 315 nm, a $\pm 10\%$ change in column ozone leads to change in irradiance of less than 5%, where the sign of the change in irradiance is opposite to that in ozone. The sensitivity to changes in ozone weakens with increasing wavelength, and at wavelengths longer than 330 nm, one can neglect absorption. As wavelength decreases from 315 nm through the UV-B, the sensitivity to changes in ozone rises dramatically. For noontime summer conditions, a 10% change in column ozone is accompanied by a 10% change in irradiance of the opposite sign at a wavelength of 308–309 nm. This increases to a doubling or halving near 295 nm, the shortest wavelengths that are readily measurable at the ground.

The largest percentage changes in Figure 5 occur at wavelengths where the absolute irradiances that reach the ground are quite small, and this is a direct consequence of the wavelength-dependent behavior of the ozone absorption cross section. One might question whether the extremely small irradiances in the UV-B are significant in view of the much larger values in the UV-A. Numerous studies have confirmed the biological importance of UV-B radiation at levels that exist in the natural environment. These investigations consistently show that the shorter-wavelength UV-B sunlight is more effective in causing damage to living tissues than are longer wavelengths in the UV-A, although radiation throughout both regions must be considered. When one combines wavelength-dependent biological sensitivities with the spectral variation of solar irradiance at the ground, the UV-B is generally the most effective region in causing biological damage, despite the small absolute energy levels. Hence, the possibility of a major

change in the ozone content of the Earth's atmosphere and the accompanying increase in ground-level UV-B radiation were a legitimate cause for concern.

Although depletion of the ozone layer is no longer a major issue, ultraviolet solar radiation remains an important environmental parameter. The chemistry of the lower atmosphere is driven by the UV-B radiation that survives passage through the stratospheric ozone layer. In this way, absorption of solar ultraviolet radiation by ozone influences the chemical makeup of the air that surrounds us. In addition, long-term exposure to natural levels of ultraviolet sunlight will continue to have biological significance.

Synopsis

Ozone depletion potentials (ODPs) is an extremely useful metric for policy considerations and scientific analyses for evaluating the relative effects of human emitted gases affecting the global atmospheric environment. ODPs arose as a simplified means for determining the relative ability of a chemical to destroy ozone. This concept for a relative measure of the cumulative impact on stratospheric ozone from trace gas emissions was found to be particularly useful by policymakers in their considerations to develop policy to protect stratospheric ozone from further destruction from emissions of halocarbons.

Introduction

Weighing functions, such as ozone depletion potentials (ODPs), are extremely useful tools in policy considerations and scientific analyses for evaluating the relative effects of human emitted gases affecting the global atmospheric environment. The scientific concept of ODPs originally arose as a simplified means for determining the relative ability of a chemical to destroy ozone (Wuebbles, 1981, 1983). This concept for a relative measure of the cumulative impact on stratospheric ozone from trace gas emissions was found to be particularly useful by policymakers in their considerations to develop policy to protect stratospheric ozone from further destruction from emissions of chlorofluorocarbons (CFCs), halons, and other relatively long-lived halocarbons. As a result, the ODP concept is an integral part of national and international considerations on ozone protection policy, including the international Montreal Protocol and its Amendments and the US Clean Air Act. The US Environmental Protection Agency and other organizations such as the United Nations Environment Programme now require evaluations of ODPs for all newly considered halocarbons, particularly for those under consideration as replacement compounds for CFCs and halons and uses as refrigerants, foam blowing agents, solvents, fire retardants, and other relevant applications where significant emissions could occur into the atmosphere.

Emissions of gases containing chlorine, bromine, or iodine can particularly affect stratospheric ozone (but not the emissions of water soluble gases like HCl that would likely be washed out of the atmosphere and not reach the stratosphere). Chlorine, bromine, and iodine react extremely efficient with ozone in catalytic processes, and these atoms can destroy thousands of ozone molecules if they reach the stratosphere. If a compound does not contain chlorine, bromine, or iodine, then it less likely to affect the stratosphere. Exceptions could occur if the compound can achieve such significant use that it would become a source of stratospheric nitrogen oxides, hydrogen oxides, or sulfuric particles.

The Concept of ODPs

The ODP of a gas is defined as the integrated change in total ozone per unit mass emission of the gas, relative to the change in total ozone per unit mass emission of CFC-11, one of the

gases of most concern to ozone change. Alternatively, the ODP can be derived by using a constant emission calculated to steady state relative to the same for CFC-11. Numerically, the two approaches are equivalent. Thus, the ODP of gas X is defined by

$$\text{ODP}(X) = \frac{\Delta\text{O}_3(X, E)}{\Delta\text{O}_3(\text{CFC} - 11, E)} \quad [1]$$

where $\Delta\text{O}_3(X, E)$ is the steady state percent change in stratospheric ozone burden due to emission at the Earth's surface of species X at E (kg year^{-1}). As a relative measure, ODPs are thought to be subject to fewer uncertainties than estimates of the absolute percentage of ozone depletion caused by different gases.

ODPs as used in the international scientific assessments on stratospheric ozone sponsored by the World Meteorological Organization (e.g., WMO, 1992, 1995, 1999, 2003, 2007, 2011) are generally determined by two different means: calculations from models, primarily from models of global atmospheric chemistry and physics, and a semiempirical approach developed by Susan Solomon and colleagues (Solomon et al., 1992, 1994). The two approaches give similar results. Until roughly the year 2000, zonally averaged, two-dimensional models of the global atmosphere were primarily used in the model determination of ODPs. More computationally intensive three-dimensional models, that represent variations with longitude as well as latitude and altitude, and that more fully represent the physics and chemistry of the atmosphere, are now used for such studies, and are the modeling tools of choice for determining ODPs. The numerical models used in such studies attempt to account for known chemical and physical processes affecting chemical species in the troposphere and stratosphere.

The compounds are assumed to enter the atmosphere at ground level, be transported in the atmosphere by dynamical processes, and react via photolysis or through reaction with other atmospheric constituents. The reactivity of the particular compound depends on its molecular structure. Generally, the compounds of interest are likely to either undergo photolytic breakdown by ultraviolet (UV) or near-UV light, react with OH in the troposphere and stratosphere, or react with atomic oxygen. There are several pathways for delivering the final products of interest, e.g., the chlorine or the bromine, to the stratosphere, as shown in Figure 1. The original compound, the source gas, can be transported directly to the stratosphere,

Figure 1 Schematic diagram of the multiple pathways that can occur, particularly for short-lived gases, to deliver halogen atoms, the final product, to the stratosphere. The dark yellow arrows indicate transport into the stratosphere, while the light blue arrows represent transport out of the stratosphere. Adapted from WMO (World Meteorological Organization), 2003. Scientific Assessment of Ozone Depletion: 2002. Global Ozone Research and Monitoring Project Report No. 47. Geneva, Switzerland, 498 pp.

where it reacts to form intermediate degradation products that then react to release the halogen atoms, or, for some reactions, release the halogen atoms directly, that can react with ozone. The long-lived gases that are well mixed in the troposphere, those with atmospheric lifetimes greater than about 1 year, have almost all of their release of halogen atoms occur in the stratosphere. For the short-lived gases, those with atmospheric lifetimes less than 1 year, there is generally enough reactivity in the troposphere that the intermediate reaction products and the final products are often produced in the troposphere. If the products are water soluble, then a high fraction can be removed by washout processes, particularly if the products are produced in the lower troposphere. However, some of these products can be transported to the stratosphere, thus allowing the halogen atoms to be available for reactions with ozone. Various research studies indicate that, for some compounds, a high fraction of the halogen reaching the stratosphere does so in the form of reaction products or as halogen atoms (Ko et al., 1997; Youn et al., 2010; Patten and Wuebbles, 2010, 2011; Wuebbles et al., 2001, 2009, 2011).

Figure 2 shows some of the important considerations in modeling the relevant chemical and physical processes to determine the stratospheric ozone depletion from emission of a halogenated compound. The processes in the large dotted box are not important for long-lived gases, but can be extremely important for short-lived gases.

A major uncertainty in the models is the amount of tropospheric hydroxyl, OH. Since few reliable measurements of OH are available, the global distribution has not been directly measured. As a result, given the importance of the atmospheric

lifetime in determining the ODP for a substance, those gases where reaction with tropospheric OH is the primary loss mechanism, as it is for many of the replacement compounds, a scaling to the partial lifetime of CH_3CCl_3 due to its reaction with tropospheric OH is often used. This scaling is generally not needed in current three-dimensional models. As discussed below, short-lived compounds, those with an atmospheric lifetime shorter than about half a year, require special consideration.

The semiempirical approach for determining ODPs is based on direct measurements of selected halocarbons and other trace species in the stratosphere. Thus, it relates ODP values to measured quantities that can also be used to evaluate the validity of the model-calculated results. The semiempirical derivation requires knowing the physical properties of the halogenated compound, its total lifetime (including loss in the ocean or on soil in addition to reactivity in the atmosphere), a factor representing the distribution of inorganic halogen released in the stratosphere obtained from observations of the compound or other compounds with similar reactivity, and an analysis of the catalytic efficiency for ozone destruction, determined relative to chlorine. The definition of the ODP of compound X using the semiempirical approach is:

$$\text{ODP}_{\text{semi-emp}}(\text{X}) = (\text{fractional release factor}) \times \frac{\mu_{\text{CFC-11}}}{\mu_{\text{X}}} \times \frac{\tau_{\text{X}}}{\tau_{\text{CFC-11}}} \times \frac{n_{\text{X}}}{n_{\text{CFC-11}}} \times \alpha \quad [2]$$

where the fraction τ is the lifetime, n is the number of halogen atoms ($n = 3$ for CFC-11), and α is the relative effectiveness of

Figure 2 Information needed for modeling the effects of emission of halogenated compounds on stratospheric ozone. Items in rectangles are compound specific. Items in ovals are common to all compounds. Items in parallelograms are model predictions. Adapted from WMO (World Meteorological Organization), 2003. Scientific Assessment of Ozone Depletion: 2002. Global Ozone Research and Monitoring Project Report No. 47. Geneva, Switzerland, 498 pp.

either bromine or iodine to destroy ozone relative to chlorine (current models suggest globally averaged α values of 60 for bromine (Daniel et al., 2011) and much larger values for iodine, as much as 500–1000). The α values are multiplied by the number of bromine or iodine atoms. While bromine and iodine atoms are much more effective than chlorine at destroying ozone, particularly in the lower stratosphere, various forms of the halogen fluorine, such as F and CF_3 , have very little effect on ozone (Solomon et al., 1995).

Note that the semiempirical approach only works for long-lived gases because it does not account for the halogen that can reach the stratosphere as intermediate reaction or final products. Therefore, this approach will be in error for short-lived halogenated compounds.

In the semiempirical approach, the observed fractional dissociation is used to determine the amount of chlorine and bromine (or iodine) released and is then compared with the observationally derived ozone loss distribution, with the assumption that the ozone loss results only from halogen chemistry. The correlation between different compounds is determined on the basis of their relative reactivity in the troposphere and stratosphere. This semiempirical method avoids some of the demanding requirements of accurate numerical simulation of source gas distributions (i.e., of the CFCs, hydrochlorofluorocarbons (HCFCs), and other compounds) and of the resulting ozone destruction. However, the semiempirical approach also depends on the accuracy of the measurements used with this approach. As mentioned earlier, the results for

long-lived gases from current models compare well with the semiempirical derivation of the ODPs.

Since ODPs are defined in terms of the steady-state ozone change (or alternatively as the integrated cumulative effect on ozone of constant emissions), they are not representative of the relative, transient effects expected for compounds during the early years of emission. For model calculations assuming constant emissions, time-dependent ODPs can also be defined where the changes in ozone for the compound and for CFC-11 are calculated as a function of time on a per unit mass emitted basis. These time-dependent ODPs provide information on the shorter timescale effects of a compound on ozone (e.g., see WMO, 1992, 1995). In the first few years after emission, the time-dependent ODP for a compound can be often be larger than the eventual steady-state value. However, the steady-state values generally are preferred and are used in regulatory considerations.

Derived ODPs

By definition, the ODP for CFC-11 is 1.0. The calculated ODPs for other CFCs are all greater than 0.4. The ODPs for halons are all extremely large, much greater than 1.0, reflecting the high reactivity of bromine with ozone. The ODPs for the HCFCs being used or considered as CFC or halon replacements are all small, with values of 0.01–0.05 and sometimes less. The effect on ozone from a unit mass

Table 1 Steady-state ODPs for some of the important chlorocarbons and bromocarbons of concern to stratospheric ozone

Gas	Chemical formula	ODP
CFCs		
CFC-11	CCl ₃ F	1.0
CFC-12	CCl ₂ F ₂	0.82
CFC-113	CCl ₂ FCFClF ₂	0.85
CFC-114	CClF ₂ CClF ₂	0.58
CFC-115	CF ₃ CClF ₂	0.57
Bromocarbons		
Methyl bromide	CH ₃ Br	0.66
Halon-1301	CF ₃ Br	15.9
Halon-1211	CF ₂ ClBr	7.9
HCFCs		
HCFC-22	CHClF ₂	0.04

Daniel et al. in WMO (World Meteorological Organization), 2011. Scientific Assessment of Ozone Depletion: 2010. Global Ozone Research and Monitoring Project Report No. 52. P.O. Box 2300. Geneva, Switzerland, 516 pp.

emission of one of these HCFCs would correspondingly be less than a 100th of the effect on ozone than the CFC or halon they would replace. ODPs for all the hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), and for sulfur hexafluoride are near zero, owing to the low reactivity of their dissociation products with ozone. **Table 1** shows ODPs for several of the gases of most concern to ozone. Replacement compounds like HCFCs and HFCs (not shown because their ODPs are close to zero) have much smaller ODPs than the CFCs and halons.

Short-Lived Compounds: Special Consideration

As discussed above, the ODP concept was originally developed for CFCs and other halocarbons whose atmospheric lifetime are sufficiently long (>1 year) so that their mixing ratios are uniform in the troposphere. However, a number of compounds now being used or being proposed as replacements for substances controlled under the Montreal Protocol have extremely short atmospheric lifetimes, on the order of days to a few months. Emissions of these compounds, generally referred to as very short-lived substances (VSLS), present special problems in determining ODPs. Most uses of these compounds are at northern midlatitudes, in the United States and Canada, Europe, or in Asia. After emission, these compounds must be transported to the tropics where they can then be transported into the stratosphere. On the other hand, emissions from locations in the tropics could have a much higher probability of reaching the stratosphere. As a result, for very short-lived compounds, ODPs are defined as a function of location (latitude, longitude) and sometimes the time (usually season) of emission. It is not adequate to treat these chemicals as if they were uniformly emitted at all latitudes and longitudes as normally done for long-lived gases. Thus, for VSLS, there is no single ODP value, but instead there should be a matrix of values, dependent on location and perhaps time, if, for example, there is a seasonal variation in the use and emission of the compound.

ODPs for a number of short-lived compounds have now been derived (see **Table 2**). An important example of a VSLS is n-propyl bromide (also referred to as 1-bromopropane, CH₂BrCH₂CH₃ or simplified as 1-C₃H₇Br or nPB). This compound, useful as a solvent, has been estimated to have an atmospheric lifetime of about 20 days annually averaged for emissions globally and 25 days for emissions from 30 to 60° N due to its reaction with hydroxyl, OH. Because nPB contains bromine, any amount reaching the stratosphere has the potential to affect concentrations of stratospheric ozone. Several studies (Olsen et al., 2000; Bridgeman et al., 2000; Wuebbles et al., 2001, 2009, 2011; Patten and Wuebbles, 2010, 2011) have noted that the idea of a single lifetime is

Table 2 Estimated ODPs for various short-lived halocarbons based on three-dimensional chemistry-climate modeling studies

Gas	Emissions latitudes	Lifetime (days)	ODP
C ₃ H ₇ Br (nPB)	60° S–70° N	19.6	0.011
	30–60° N	24.7	0.0049
C ₂ Cl ₄ (PCE)	30–60° N	111	0.0060
C ₂ HCl ₃ (TCE)	30–60° N	13	0.00035
C ₃ H ₂ F ₃ Br (BTP)	60° S–60° N	4.3	0.0052
	30–60° N	7.0	0.0028
CH ₃ I	30–60° N	13.6	0.017
CF ₃ I	30–60° N	5.0	0.008

flawed for very short-lived compounds – mixing ratios of nPB reaching the tropical upper troposphere depend strongly on the latitude and season of the emissions. These studies found that tropical emissions were twice as likely to enter the stratosphere as high-latitude emissions. Wuebbles *et al.* (2001) showed that up to 0.5% of the Br emitted as nPB at the surface entered the stratosphere, with only 20–30% of Br in the form of nPB. The remainder was in the form of reaction products or inorganic bromine. These studies also emphasize the importance of knowing the degradation products in quantifying their contribution to halogen loading in the stratosphere.

After emission, generally over continents at midlatitudes in the Northern Hemisphere, short-lived chemicals like nPB are not expected to have well-mixed concentrations in the troposphere. Winds and other mixing processes in the atmosphere would gradually transport these gases to the tropics where they can most effectively be transported to the lower stratosphere. At the same time, because of the short lifetime, reaction with OH and other chemical loss processes would convert a significant fraction of the chemical emitted to its degradation products. The processes affecting resulting degradation products could be quite important as they could act as vehicles for transporting chlorine or bromine to the lower stratosphere. The inorganic bromine compounds produced from tropospheric nPB degradation, if not sufficiently removed by wet deposition, could contribute further to stratospheric bromine. The question of how much of the halogen that would be available to affect stratospheric ozone therefore depends greatly on the complex effects of transport and chemical processes in the troposphere.

Evaluations of ODPs for short-lived compounds with three-dimensional chemical transport models of the troposphere and stratosphere are needed for such short-lived gases. In theory, these models should be able to effectively determine the amount of a short-lived chemical compounds and its degradation products reaching the stratosphere and the resulting potential effects on ozone. The models that have complete representations of stratospheric chemical and physical processes are computationally intensive.

Table 2 compares the ODP values derived for several chemicals with short atmospheric lifetimes using three-dimensional models with complete representation of tropospheric and stratospheric processes. In general, the ODPs for such short-lived compounds tend to be much smaller than those for the ODPs and their first generation replacements, the HCFCs (as seen by comparing with **Table 1**). With the use of CFCs and HCFCs now largely banned because of the concerns about stratospheric ozone, replacements for those compounds need to be found. Given their very short lifetimes, the direct effects on climate from such short-lived compounds also are very small. As a result, it is likely that industry will be turning to consideration of such very short-lived compounds for the various uses as refrigerants, foam blowing agents, solvents, fire retardants, and other relevant applications.

Synopsis

The photodissociation of ozone in the UV–visible is reviewed and the photochemical processes are identified. Especially the formation of atomic oxygen atom in the first electronically excited state, $O(^1D)$, plays an important role in the lower atmosphere, since it is the dominant precursor of the formation of OH radicals in the lower atmosphere. Experimental studies of the determination of the $O(^1D)$ quantum yield, predominantly performed in the wavelength range 305–355 nm, are presented. The atmospheric implications of the wavelength and temperature dependence of new $O(^1D)$ quantum yields are discussed.

Introduction

Ozone is one of the most important constituents of the Earth's atmosphere (from here on just referred to as the atmosphere). It plays several major roles in the atmosphere that include shielding the Earth's surface from harmful UV radiation, acting as a greenhouse gas, and generating reactive free radicals such as OH, which oxidize and remove pollutants from the atmosphere. Each of these important roles involves the absorption of photons by ozone and hence the importance of ozone photochemistry.

Role of Ozone in the Atmosphere

Absorption Spectrum

Ozone absorbs radiation from the vacuum ultraviolet (VUV) throughout the UV and visible regions and into the infrared. However, photodissociation of ozone in the atmosphere is mostly due to absorption of visible and shorter wavelength radiation. The absorption spectrum of ozone in the visible and UV regions is shown in [Figure 1](#) and is based on the data from a variety of sources.

The ozone absorption spectrum in the 200–900 nm region can be attributed to four systems: the Hartley band (UV), the Huggins bands (near UV), the Chappuis band (visible), and the Wulf band (near infrared). [Orphal \(2003\)](#) and [Sander et al. \(2011\)](#) have published reviews of available spectra measured over the temperature range 200–300 K. Absorption shown in [Figure 1](#) involves the excitation of ozone from the ground electronic state to an excited electronic state from which it dissociates to an oxygen atom and an O_2 molecule. It is, however, possible for ozone to split apart into three O atoms below ~ 197 nm; however, such a three-way dissociation is not important in the atmosphere except at very high altitudes. It is also possible for ozone to reemit the absorbed light (fluoresce); such emission seldom occurs.

Special Role of $O(^1D)$ Atoms in the Atmosphere

Generally speaking, species in excited states do not play a major role in the chemistry of the Earth's lower atmosphere (i.e., below about 40 km). The most notable exception is the oxygen
